ABSTRACT

Chronic rhinosinusitis (CRS) with nasal polyposis (NP) is a common chronic disease that often affects maxillary sinus. Endoscopic sinus surgery (ESS) is the most common procedure to treat the maxillary sinus lesions by a middle meatal antrostomy (MMA) and the introducing of new microdebrider blades of 15, 40, 70, and 120° improved this approach.

Nevertheless in some cases, angled microdebrider are not sufficient and canine fossa puncture (CFP) is performed as an alternative method to obtain a complete access to the maxillary antrum.

INTRODUCTION

Chronic rhinosinusitis (CRS) with nasal polyposis (NP) is a common chronic disease that seriously affects the quality of life [1]. The blockage of the ostiomeatal complex is the most common factor influencing the pathogenesis of this inflammatory process [2]. Endoscopic

sinus surgery (ESS) is the most common procedure for treating CRS that is refractory to medical treatment.

Although the majority of maxillary sinus lesions can be removed through the widened natural ostium performing partial uncinectomy and middle meatal antrostomy (MMA), some patients have extensive disease that is difficult to handle purely endoscopically.

In fact, endoscopic surgery of natural ostium allow to clear the posterior lateral wall, the posterior region of the roof, and the posterior wall of the maxillary sinus but no anterior and inferior regions. Failure to remove massive polyposis and fungal debris from the maxillary sinus may result in an early postoperative recurrence of symptoms and disease for the patient [3].

One solution is the traditional Caldwell Luc approach performed through the anterior wall of the maxillary sinus. However, this is associated with significant morbidity such as facial numbness or paresthesia (9%) for damage of the infraorbital and anterior superior alveolar nerves, oroantral fistulas (1%), gingivolabial wound dehiscences (1.5%), and dacryocystitis (2.5%). This technique has been outdated by endoscopic medial maxillectomy useful to treat benign tumors, not inflammatory disease [4]. Canine fossa puncture (CFP) has been proposed as an alternative method of obtaining access to the maxillary antrum.

Although few studies have demonstrated the benefits of CFP in management of the severely diseased maxillary sinus, the efficacy and superiority of this method compared with conventional MMA, require further investigation above all considering new microdebrider blades of 15, 40, 70, and 120° that can be inserted through the antrostomy [5].

The aim of this study is to review the literature about the indications of CFP in patients with severe maxillary sinus disease and compare this surgical procedure with maxillary sinus clearance through MMA.

CANINE FOSSA PUNCTURE TECHNIQUE

CFP consist in a trocar placed in the canine fossa [6]. The landmarks in canine approach are: the mid pupillary line and horizontal line running along the lower border of nasal ala and lateral aspect of canine fossa high above the 3rd and 4th teeth (canine and premolar), infero lateral to infra orbital foramen. The trocar should be aimed towards the maxillo ethmoid angle to avoid pterygopalatine fossa and orbital lesions. In most patients the trocar was inserted using a gentle twisting motion. In some patients with thicker bone, gentle tapping with a hammer was required for the trocar to be inserted [7, 8]. After removal of the trocar a 4-mm microdebrider blade was placed through the passage created by the trocar. The microdebrider blade was visualized in the maxillary sinus with a 40 or 70° endoscope via the middle meatal antrostomy. Polyps and diseased tissue can be removed from the maxillary sinus using the microdebrider.

DISCUSSION

Nowadays, middle meatal antrostomy (MMA) is considered the gold standard in the treatment of maxillary sinusitis. Anyway critical areas such as inferior, lateral, anterior wall, recessus zygomaticus and recessus alveolaris and recessus prelacrimalis of maxillary sinus

are difficult to approach. For this reason, medial maxillectomy or external approaches such as Caldwell Luc approach or CFP are required [6].

The efficacy of this manoeuvre on the outcome after FESS has been investigated in few studies. Lee et al have compared the results of performing a canine fossa puncture with clearance of polyps via a middle meatal antrostomy. No benefit of the canine fossa procedure over conventional middle meatal antrostomy was seen after 12 months follow up, however series are small in both groups (11 CFP V.S. 13 MMA). The authors concluded that although canine fossa puncture is a useful method for removing severe mucosal disease that cannot be reached through the MMA, it does not guarantee a better subjective or objective surgical outcome in patients with nasal polyposis [3]. However, Seiberling et al in a case control studies have found that patients with the same disease who had a canine fossa puncture had a better outcome than those who did not. In fact, all patients were administered the chronic sinusitis survey (CSS) that evidenced a subscore better in the CFP group (Mann-Whitney test, $P = 0.02$) [9].

In the last years, the advent of angled microdebrider blade (15, 40, 70, 120°) modified sinus endoscopic surgery allowing to reach critical areas of maxillary sinus but we have few references in literature that compare these instruments with CFP approach. Beswick et al quantified the maxillary sinus volume and mucosal surface area (SA) that is accessible endoscopically via a middle meatal antrostomy in eight cadaver maxillary sinuses configured with image guidance software. In particular the authors demonstrated that mean maxillary sinus volume was $16.5 \pm 2.5 \text{ cm}^3$ and mean SA was $31.0 \pm 2.3 \text{ cm}^2$. The 15, 40, 70 and 120° microdebriders accessed an average of 10, 25, 41, and 66%, respectively, of the SA, and of 2, 9, 17, and 36%, respectively, of the volume. There was a trend toward improved accessibility of the superior half versus the inferior half of the maxillary sinus. When instruments of different degrees were combined to maximize accessibility, 81% of the SA of the sinus could be accessed. However authors did not quantify volume and area of maxillary sinus exposed [10].

Feldt et al in a sample of cadavers showed that a significant greater amount of debris was left after the transnasal endoscopic technique (TN) approach compared with canine fossa trephination (CFT) (3.88 cm^3 vs 2.88 cm^3 , $p = 0.015$). Median blade utilization was significantly higher with the TN approach vs CFT (4 vs 1, $p < 0.002$).

Therefore, although using new curved blades, critical areas such as antero-medial portion of MS cannot be reached and treated by antrostomy and therefore CFP has to be performed. According to literature, CFP can be performed only in unilateral lesions. In fact Byun et al assigned randomly twelve patients to the CFP and thirteen to MMA groups who completed the follow-up, questionnaires (SNOT-20 and VAS), and postoperative CT evaluation. SNOT-20 and VAS scores improved significantly at 3, 6, and 12 months postprocedure in both groups. However, significant improvement of SNOT-20 at 12 months and VAS scores for purulent discharge, foul odor, and postnasal drip at 6 and 12 months were observed in the CFP group compared with the MMA group. Postoperative CT scan evidenced that the volume of mucosal thickening was significantly greater in the MMA group than in the CFP group. In addition, CFP was not effective in patients with bilateral CRS and diffuse NP but provided better management and subjective and objective surgical outcomes in patients with unilateral CRS accompanying NP 2. Among unilateral NP, there are antrochoanal polyps (ACP). ACP is relatively unusual in the sinonasal tract. It occurs predominantly in children and young adults and originates from the maxillary antrum with extension into the nasopharynx or

oropharynx. Simple excision of the polyp via limited surgical procedures such as simple polypectomy results in high recurrence rates. Complete removal of the polyp in the antrum, including its site of origin, is essential to minimize recurrence. However, a broad base such as a lateral, inferior, or anterior location of the polyp makes eradication difficult via a MMA. In this situation, some authors choose the traditional Caldwell-Luc operation, even in children [11]. However, the increased morbidity of this procedure, including facial numbness, facial swelling, risk for injury of the tooth buds and roots, and possible asymmetric facial growth, makes it less favorable than endoscopic sinus surgery. In fact, CFP is considered an alternative method of accessing almost the entire maxillary antrum in young/adult population. Few studies have reported the efficacy of the CFP approach in treating ACP in the pediatric population (≤ 15 years old) and the long-term effect on changes in the maxillary sinus volume and surgical outcome has not been determined. Jae Yong Lee et al studied a little sample of seven patients with ACP removed via the CFP approach. After a mean follow-up period of 43.9 months, the authors compared the changes in the maxillary sinus volume between the operated and normal sides, using the pre- and postoperative CT data. No contractures or decrease in the maxillary sinus volume on the diseased side were observed in any of the patients on postoperative CT. None of the patients showed evidence of recurrence on the endoscopic and CT examinations and only two patients complained of mild facial swelling and tingling sensation, which resolved spontaneously within 2 weeks [13]. Therefore, CFP can be performed to treat ACP in young but also in children when MMA is not sufficient.

Important indications to CFP are chronic odontogenic sinusitis (COS). Approximately 5–15 % of the population suffers from chronic rhinosinusitis, and in 10–12 % of them, it is of dental origin [13]. It is produced by periapical granulomas or small inflammatory cysts of the molars or bicuspid, chronic oroantral fistula (OAF), large odontogenic cysts occupying a great part of the maxillary sinus, and foreign bodies (dental fillings, teeth roots, and implants) pressed throughout the root canal or fistula into the antrum.

Venetis et al presented 20 cases with odontogenic sinusitis, 5 (25%) in which a foreign body was removed from maxillary sinus by combined transnasal and canine fossa endoscopic approach. The surgical procedure was performed with conventional instrumentation through the widened antrorhinostomy or through a bony window at the anterior sinus wall. At the end of the procedure, the window was repositioned and stabilized with two to three absorbable sutures. In two cases, with sizeable foreign bodies, the preservation of the bony window was impossible, and a modified Caldwell–Luc operation was performed with preservation of the healthy sinus mucosa [14]. According to Barzilai et al we avoid Caldwell–Luc operation because it is associated with significant morbidity such as facial numbness or paresthesia (9%) for damage of the infraorbital and anterior superior alveolar nerves, oroantral fistulas (1%), gingivolabial wound dehiscences (1.5%), and dacryocystitis (2.5%) [15]. Actually, Caldwell-Luc procedure is rational in cases of fungal disease and in endoscopic medial maxillectomy for treating inverted papilloma.

In the literature, different opinions about approach to fungal maxillar sinusitis are reported. In most of the patients it can be removed through the MMA using various curved instruments and saline irrigation without great difficulty. Also, if fungal invasion into sinus tissue is confirmed by histological examination, a systemic antifungal treatment postoperatively is paramount to reduce disease and potential recurrences [16].

Instead, there are no indications to perform CFP and/or Caldwell- Luc approach in maxillar sinus malignant tumor. According to the literature, endoscopic medial maxillectomy

can be considered as first choice in difficult maxillary sinus tumor removal because an unnatural opening like CFA or Caldwell Luc in locally invasive disease with malignant potential as the tumor can extend through this opening in recurrent cases [17, 18, 19, 20, 21].

CONCLUSION

Although angled microdebrider improved endoscopic approaches to maxillary sinus, literature showed that canine fossa puncture is a minimally invasive technique useful in selected cases and without postoperative complications.

ABSTRACT

Endoscopic sinus surgery (ESS) is one of the most commonly performed procedures in otolaryngology. ESS complications should be distinguished in minor and major based on the treatment they need and the permanent sequelae they can cause. Over the years it has gone from an incidence of complications in endoscopic surgery of 8% for the major and 21% for the minor to a percentage of 0 -1.5% and 1.1-20.8%, respectively. This is due to the considerable diffusion of the technique with a progressive increase over the years of the surgical experience but their presence help to educate otolaryngologists and patients about complication rates in ESS in a modern context. A complication occurs when injuries to anatomical structures defined in the literature “risk areas” are created. The surgeon must know and identify these areas because these are important land mark that guide our interventions respecting the anatomical boundaries.

The aim of this chapter is to describe principle complications and their management.

* Corresponding Author's Email: federicosireci@hotmail.it.

INTRODUCTION

“An undesirable, unintended and direct result of an operation affecting the patient which would not have occurred had the operation gone as well as could reasonably be hoped” [1]. This is the current definition of surgical complication. These are distinct and classified according to gravity in 5 degrees [2].

FESS complications should be distinguished in minor and major based on the treatment they need and the permanent sequelae they can cause (Table 1) [3, 4].

Over the years there has been an incidence of complications in endoscopic surgery of 8% for the major and 21% for the minor at a percentage of 0 -1.5% and 1.1-20.8%, respectively. This is due to the considerable diffusion of the technique with a progressive increase over the years of the surgical experience. Ramakrishnan et al. in a 2012 retrospective study of 63823 patients report the following percentages for major complications: 0.17% rhinoliquorrea, 0.07% orbital lesions, 0.76% massive hemorrhage with need for transfusion [4, 5]. Regarding the complications in pediatric age, they are negligible with percentages below 1%, especially if the synechia are excluded. [6]. A complication occurs when injuries to anatomical structures defined in the literature “risk areas” are created. The surgeon must know and identify these areas because these are not actually such, but they are important points of reference that guide our interventions respecting the anatomical boundaries. At present the major risk areas are summarized by the acronym “CLOSE” (C = Cribriform plate; L = Lamina papiracea; O = Cell onodi; S = Sphenoid; E = anterior ethmoidal artery) [7].

To better understand the possible complications, we will avoid addressing them by referring to this acronym but we will describe the main FESS steps highlighting for each of these the possible risks.

Table 1. Classification of surgical complications according to Dindo et al.

Grade	Definition
Grade I	Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic, and radiological interventions Allowed therapeutic regimens are: drugs as antiemetics, antipyretics, analgetics, diuretics, electrolytes, and physiotherapy. This grade also includes wound infections opened at the bedside
Grade II	Requiring pharmacological treatment with drugs other than such allowed for grade I complications Blood transfusions and total parenteral nutrition are also included
Grade III	Requiring surgical, endoscopic or radiological intervention
Grade IIIa	Intervention not under general anesthesia
Grade IIIb	Intervention under general anesthesia
Grade IV	Life-threatening complication (including CNS complications)* requiring IC/ICU management
Grade IVa	Single organ dysfunction (including dialysis)
Grade IVb	Multiorgan dysfunction
Grade V	Death of a patient
Suffix “d”	If the patient suffers from a complication at the time of discharge (see examples in Table 2), the suffix “d” (for “disability”) is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.

*Brain hemorrhage, ischemic stroke, subarachnoid bleeding, but excluding transient ischemic attacks.
CNS, central nervous system; IC, intermediate care; ICU, intensive care unit.

Table 2. Classification of complications of nasal sinus surgery

Minor complications	Major complications
<i>Temporary (not to be treated)</i>	<i>Treatable</i>
- Subcutaneous periorbital emphysema - Periorbital bruising - Dental and/or labial pain/paresthesia	- Orbital hematoma - Reduction of the visus - Diplopia - Epiphora (which requires dacryocystorhinostomy) - Bleeding that requires transfusion - Liquorrea - Meningitis - Brain abscess - Focal cerebral hemorrhage
<i>Temporary (to be treated)</i>	
- Symptomatic synechia - Epistaxis - Pranasal sinus infections	
<i>Permanent</i>	
- Pain/paresesia dental and lip - Loss of smell	<i>Not treatable</i>
	- Death - Blindness - Diplopia - Central nervous system deficiency

UNCINECTOMY

During this maneuver the risk areas are two: the lamina papiracea and the lacrimal duct (Figure 1).

CT scan is important to study the lamina papiracea in subjects who have never undergone surgery or who have had facial trauma because they may present spontaneous dehiscences or protrusions of the orbital fat within the ethmoid or maxillary sinus.

Figure 1. Risk areas during uncinectomy. The uncinate process is highlighted in red; in yellow the lamina papiracea.

Figure 2. a) Spontaneous dehiscence of lamina papyracea; b) Lamina papyracea dehiscence in a patient with chronic rhinosinusitis.

Figure 3. Medial wall of the maxillary sinus very lateralized with respect to the lamina papyracea.

Important is the evaluation of the projection of the medial wall of the orbit on the medial wall of the maxillary sinus. If the medial wall of the maxillary sinus is lateralized respect to the orbit (as in the “Silent Sinus Syndrome”), the uncinate process will be horizontalized, lateralized and leaning against the lamina papyracea. In these cases, during the uncinectomy, a downward correction of the backbiting forceps is necessary to avoid damaging the papyracea lamina and entering the orbital environment through the inferior-medial angle of the orbit.

Intraoperative safety measures are the execution of the Stankiewicz maneuver that allows us to evaluate infractions of the lamina papyracea and the use of the debrider with a tangential direction respect to orbit in order to prevent the aggression of endoorbital structures. The use of the scalpel to dissect the uncinate process is by now a disused technique because it increases the risk of violating the orbital environment. Nasolacrimal duct lesion is a rare complication not reported in the latest cases because the hardest consistency of nasolacrimal bone is easily perceived by the operator. However, if it should be damaged, it is important to perform a dacryocystorhinostomy (DCR) intraoperatively to ensure proper drainage of lacrimal secretions. An untreated nasolacrimal duct lesion manifests clinically in the immediate postoperative period but in these cases a follow-up of some months (3-6 months) is recommended because often the epiphora resolves spontaneously. Only in 15% of cases can it occur even after the postoperative period [8, 9].

MIDDLE ANTROSTOMY

In addition to the risk areas described for the uncinectomy, it is possible to damage the sphenopalatine artery. This artery emerges from the sphenopalatin foramen delimited by the orbital process and the sphenoid process of the palatal bone placed in the posteromedial corner of the maxillary sinus. Therefore it is important to have an appropriate equipment (dessy bipolar forceps). The sphenopalatine artery and its septal branch vascularizes the posterior portion of the nasal septum that can be used as a closing flap in the skull base surgery, therefore it is desirable to preserve them. In surgical procedures within the maxillary sinus, other risk areas are the maxillary artery behind posterior wall of the maxillary sinus, the infrorbital nerve (V2) that runs in the median portion of the orbital floor and the superior alveolar nerve on the floor of maxillary sinus [10, 11, 12].

FRONTAL SINUS

The risk areas are represented by the anterior ethmoid artery and the lateral lamella of the lamina cribra.

The anterior ethmoid artery is a branch of the ophthalmic artery that runs from the orbit to the endocranium passing through the ethmoid roof. Anatomical studies on cadaver evidenced that in 91% of cases it is located inside the cranial base, therefore protected by the bone structure, while in 9% of cases it runs inside a mesentery suspended below the cranial base and therefore it is partial or total dehiscence [13].

The artery runs behind the first ethmoid foveola and often is protected by the cranial portion of the ethmoid bulla therefore frontal recess can be opened without decomposing the bulla can represent a measure of safety. The lesion of this artery can lead to an early intra or post-operative bleeding or to a massive intraorbitaly bleeding with suffering of the optic nerve. For this reason, in the surgery of the frontal recess, the use of sharp instruments is recommended. In case of direct lesion of the anterior ethmoidal artery, it is sufficient to cauterize it with a bipolar forceps, possibly with a three or four-handed operation to maintain cleaned operating field, allowing an optimal visualization of the bleeding point. If the artery is retracted into an orbit by causing an intra-orbital hematoma, a lateral cantotomy of urgency can prevent the loss of visual function.

Figure 4. Dehiscent anterior ethmoidal artery in the left nasal fossa.

Figure 5. Rhinoliquoral fistula on the roof of the right nasal fossa ethmoid.

The lateral lamina of the cribra is very thin and in this area the dura mater is adherent to the periosteum so that a minimal bone infraction causes a tear of the dura with consequent rhinoliquorrea. In the preoperative planning it is important to evaluate the orientation and the length of the lateral lamina. Keros proposed an anatomical classification that measures the height of the lamina itself respect to the ethmoidal fovea determining so the depth of the olfactory fossa. There are 3 type: Keros I (1-3 mm) present in 12%; Keros II (3-7 mm) present in 70% and Keros III (7-16 mm) present in 18% [13]. A very long lateral lamina with a deep olfactory fossa increase surgical risk. Another parameter to be evaluated is the anatomical orientation of the lamina itself: if the lateral lamina is in a horizontal position, greater is the risk of CSF. It should also be noted that in 12% of patients there is an asymmetry between the two sides of 2 mm and that in about 6% of cases there are spontaneous dehiscences of the ethmoid roof [13]. In the frontal recess surgery safety measures are keeping intact, if possible, the ethmoid bulla, the use of sharp instruments and the execution of maneuvers from posterior to anterior and from medial to lateral.

If a CSF occurs, it must be recognized and repaired immediately in order to avoid further complications such as meningitis and/or pneumoencephaly. The administration of intrathecal fluorescein, useful in the exact topodiagnosis of a fistula, is not necessary if the diagnosis of the complication is intraoperative while it is advisable if the diagnosis is post-operative. The repair of an iatrogenic fistula of the lateral lamina involves the isolation of the area of the liquorrea, the preparation of the area bordering the defect, demucosization of the surrounding areas, removing all the bony asperities in order to obtain a more homogeneous operative field and that allows the placement of the graft. The use of autologous grafts that allow a correct integration of the graft into the receiving site is preferable. For small fistulas (3mm) it may be sufficient to use an overlay technique using mucoperiosteal taken from the septum or middle turbinate. In the larger size fistulas a multilayer technique is used, regularizing the bone edges and using the muscular fascia (fascia or temporalis muscle fascia) to better activate the function of the fibroblasts. The use of biological glues is not to be considered a closing technique but can be useful in stabilizing the grafts using it as a glue of the edges of the same. Nasal packing with the purpose of supporting the grafts must also be avoided, because their positioning and/or removal can lead to dislocation of the grafts themselves. In the literature are also described cases of occult liquorrea with spontaneous resolution with a reported percentage of 3% [15].

ETHMOIDECTOMY

The anterior ethmoidectomy provides for the opening and removal of the ethmoid bulla after the breakdown of the uncinate process. The risk areas are laterally the lamina papyracea and above the anterior ethmoid artery and the lateral lamina of the lamina cribra. Papyracea lamina lesions may result in orbital complications. The appearance of post-operative orbital ecchymosis is frequent. This complication does not compromise the orbital function and should be treated with the early nasal molding, the administration of broad-spectrum antibiotic and reminding the patient not to blow their nose for at least 20 days in order to avoid orbit emphysema. The presence of pneumorobita must be monitored because if it is stable it does not require further treatment whereas if it is evolving it may require the insertion of needles aspiration through the transpalpebral way to decrease the orbital tension caused by emphysema.

In case of exposure of orbital fat, it is recommended to refrain to reposition it to the endorbital level and to limit the cauterization of herniated fat. Parameters that must be evaluated in case of orbital complication are the perception of the red color that indicate a lesion of optic nerve, the diplopia and the orbital pain of ocular movements, possible index of damage to the extrinsic orbital musculature. Safety measures in the decomposition of the bulla are its opening in the inferior medial angle, its subdivision in the medium lateral direction with sharp instruments and the use of the debrider with a tangential direction to the orbit itself.

Posterior ethmoidectomy involves the decomposition of the second portion of the basal lamina of the middle turbinate. The risk points in this case are the lower wall, the lamina papyracea, the ethmoid roof and the sphenoidal etmoid interface. Excessive removal of the inferior wall, formed by the third portion of the basal lamina of the middle turbinate, causes a destabilization of the middle turbinate itself which can lateralize and close the posterior ethmoid with the consequent formation of iatrogenic mucocoeles. Regarding the lamina papyracea are worth the considerations made for the anterior etmoidectomy, remembering that the closer you get to the orbital apex, the more the medial rectus muscle approaches the papyraceae, thus increasing the risk of damage to the ocular muscles. The ethmoidal roof at the junction between posterior ethmoid and the sphenoid planum is frequently found in a lower plane with respect to the anterior etmoid simulating a sort of “hammock” stretched between these structures. The evaluation of the ethmoid roof trend must be made with the CT scans in sagittal projection in order to avoid a lesion of the ethmoid roof with consequent liquor fistula. Another possible site for complications at the ethmoid roof is the posterior ethmoidal artery. This usually occurs in a bone channel near the ethoidosphenoidal junction. One of his lesions is a rare occurrence. At the level of the ethmoid sphenoid interface the presence of Onodi cells should be evaluated. This is a cell of the posterior ethmoid, present between 4-42% of patients, which pneumatizes the supero-lateral face of the sphenoid sinus and may contain the optic nerve inside (4-8% of cases) and in rare cases the dehiscent internal carotid artery which are therefore at risk of injury during posterior ethoectomy [16]. The Onodi cell should be evaluated by comparing the three projections of the CT. Its incorrect evaluation may lead to optic nerve lesions and/or cataclysmic hemorrhages caused by internal carotid lesions.

Safety measures in the posterior ethoidectomy are its opening in the inferomedial angle of the second portion of the middle turbinate and therefore its decomposition in the first later lateral direction then using sharp instruments and making a lower correction in the decomposition of the most cranial portion. If surgical measures are required in the posterior portion of the posterior ethmoid it is advisable to first perform a sphenoidotomy to identify lateral and upper anatomical limits.

The surgical operations performed on the middle turbinate provide for a partial removal, for correction of a paradoxical curvature, a removal of its lateral component, in case of decomposition of a bullosa or subtotal removal, if the pathology to be treated requires the creation of large cavities. The risks in the treatment of turbinates are represented by its cranial insertion and its relationship with the olfactory shower. Torsion maneuvers can lead to a destabilization of the middle turbinate, which lateralizes in the postoperatrix, predisposing to the formation of mucocels or even causing a fracture of its cranial insertion with lesion of the dura mater and rhinoliquorrea. The section of the middle turbinate must always be conducted inferiorly to a line passing through the armpit of the turbinates (middle, upper and upper) so as to respect the lamina of the croissants seat of the olfactory mucosa. In the decomposition of the medium turbinate it is advisable to use sharp tools, the progressive decomposition of the same avoiding rough maneuvers and the respect of the lamina of the croissants keeping a lower level to the lamina itself.

SPHENOIDOTOMY

The sphenoidal sinus can be approached with two main approach: the direct paraseptal and the transetmoidal [17]. The common point of the two approaches is the identification and enlargement of the natural sphenoid sinus ostium. A non-natural sphenoid opening may expose the optic nerve to damage because the anterior wall of the sphenoid is inserted laterally and perpendicular to the orbital apex. This perpendicular insertion may determine, in case of fracture at its insertion point, an injury to the orbital apex by the insertion of bone spicules. The finding of the natural ostium provides further security of the surgical maneuvers in the presence of Onodi cells.

In the direct paraseptal transnasal approach, the landmarks are represented from the choanal border, then continuing vertically and medially to the tail of the middle turbinate, the tail of the superior and superior turbinate. The natural ostium of the breast is located at the top of the upper turbinate. This, depending on the pneumatization of the sphenoidal rostrum, can be felt in a medial position, and therefore directly visible, or in a more lateral position, hidden from the tail of the upper turbinate itself. The risk points in this approach are the posterior portion of the olfactory area and the sepal branch of the sphenopalatine artery on the anterior wall of the sphenoid itself. A lesion of the olfactory area may result in alterations in the olfactory function and if the anatomical disorientation continues, a lesion of the skullbase with consequent rhinoliquorrea. A lesion of the sepal branch of the sphenopalatine artery leads to a hemorrhage of simple control but compromises the vascularization of septal flaps useful in the reconstruction of the cranial base. Safety measures are the finding of the natural sphenoid sinus ostium maintaining a direction of the instruments parallel to the plane of the nasal floor and the visualization of the axilla of the superior turbinate that identifies the

olfactory area. The septal branches start in an area that moves from the lower portion of the upper turbinate to the upper portion of the middle turbinate tail. Their preservation can be achieved by limiting the sphenoidotomy to an upper plane with respect to the vascular area or, if necessary a wider sphenoidotomy, looking for the subperiosteal plane of the anterior wall of the sphenoid and by detaching the mucoperiosteal in caudal direction exposing the bone wall which at this point it can be removed up to the coanal edge, preserving the vascularization.

In transetmoidal way, the landmarks are, after the opening of the posterior ethmoid, represented in sequence by the body of the superior turbinate, by its tail and then by the natural ostium of the sphenoid sinus. The superior turbinate is to be found in the medial and inferior portion of the most anterior portion of the posterior ethmoid. Once the upper turbinate body has been identified, it continues in its progressive section up to the finding of the natural sphenoid ostium. The risk areas are the same as those of the transnasal route (olfactory area and the septal branch of the sphenoplatin artery). Safety measures are the finding of the middle turbinate axilla that indicates the olfactory region, the correction of the section plane in caudal direction parallel to the nasal floor. The insertion of a curved instrument at the level of the sphenoethmoid recess and its finding by transetmoidal way provides us with a further security of the correct finding of the superior turbinate and of the ethmoidal sphenous recess.

The sphenoid sinus has a wide variability of its pneumatization. The risk areas are represented by the anatomical structures of the neighboring regions that imprint, more or less clearly, the profiles of the walls of the sphenoid. The most critical area is represented by the lateral wall where the internal carotid artery and the optic nerve run. These can be dehiscent and therefore more exposed to iatrogenic lesions [18, 19, 20, 21]. For a correct anatomical orientation it is necessary to identify the intrasphenoidal points of recognition which indicate the position of the confined anatomical structures.

ABSTRACT

Sphenoid sinus is very close to important and vulnerable structures of the skull base and therefore a delayed diagnosis and treatment can be potentially lethal. Endoscopic sinus surgery is a safe and effective technique that allows a direct route to the sphenoid sinus and therefore is considered the gold standard for the surgical approach to this region. Over the years, the indications for transnasal approaches in skull base surgery have extended in order to obtain an adequate resection of the pathology as with other conventional approaches, with a minor morbidity and an equal efficiency.

Many classifications, divided in base of intracranial pathology or intracranial anatomical landmarks, have been proposed to define the transnasal corridors in base of the localization through the middle cranial base. In this chapter, we propose a review of classification of transsphenoidal skull base approaches and show the main transnasal

corridors to the sphenoid sinus based on the anatomical sphenoidal target and extension of pathology.

INTRODUCTION

Endoscopic surgery of the sphenoid sinus has been a great challenge in the past years for both otorhinolaryngologists and neurosurgeons, because of the difficulty in performing surgical maneuvers in a deep space (sphenoid sinus) through narrow structures (nasal cavities).[1-3].

Otorhinolaryngologists have used the endoscopic techniques to replace the conventional “open” approaches since early '80s [4, 5]. Metson et al. reported in 1996 a direct approach to the sphenoid sinus thanks to the development of rigid nasal scopes and the evolution of the technologies [6, 28].

Jho et al. in the '90s proposed a pure endoscopic transnasal paraseptal approach for the treatment of pituitary adenomas [7]. In the early years of this experience, the corridor used was a direct transnasal approach from one or two nostrils [8-11].

The cooperation of multidisciplinary groups, the experiences in anatomical cadaveric endoscopic study and the improvement of technologies and endoscopic instrumentations have led to an extension of the surgical indications [12-17, 28-30].

In the last ten years, many classifications of transnasal corridors in skull base surgery have been proposed [18-23].

Extended sellar and parasellar endoscopic surgery needs a preoperative planning of the surgical corridor, and this planning should be based on the anatomical sphenoidal target.

In this chapter we propose a classification of the surgical corridors in the transsphenoidal skull base surgery, based on the anatomical subdivision of the sphenoid sinus into four regions

1. NASAL CORRIDORS

In transsphenoidal skull base surgery, a wide exposure of the sphenoidal landmarks is required to avoid surgical complications.

There are three main surgical corridors to this region:

- Direct transnasal (paraseptal);
- Transethmoidal;
- Transethmoido-pterygoidal.

To simplify the approaches, we divide the sphenoid sinus into four anatomical regions: sellar region, lateral parasellar region, suprasellar region and clival region.

1.1. Direct Transnasal (Paraseptal) Corridor

This approach to the sella allows a rapid access to the sphenoid sinus by using the natural way of access to the sphenoidal ostium. When advancing tangentially through the nasal cavity, the first anatomical landmark is the choanal border. Then, proceeding vertically medial to the middle turbinate, the second anatomical landmark to seek is the tail of the superior turbinate. Sphenoidal ostium is located superomedially and dorsally to the tail of the superior turbinate. After its identification, the natural sphenoidal ostium is opened inferomedially using circular forceps, microdebrider or nasal drill.

When the natural ostium has a lateral position and it is not clearly visible, the access to the sphenoidal cavity is obtained with a transrostral approach: in this case, the anterior sphenoidal wall is drilled directly medially and superiorly the tail of superior turbinate in order to avoid lesions of the choanal branch of the sphenopalatine artery, then the removal of anterior wall of sphenoid sinus proceed superolaterally to reach natural ostium.

1.2. Transethmoidal Corridor

In this approach, the sphenoidal ostium is reached through the dissection of the ethmoidal cells. The surgical procedure begins with uncinectomy, antrostomy and ethmoidal bulla removal. The second step is the opening of the posterior ethmoid, after the identification of the second portion of the middle turbinate (an essential anatomical landmark). The access to the posterior ethmoid sinus is obtained penetrating the second portion of the middle turbinate in a medial and inferior position with a j-courette and then enlarging with circular forceps. The third step is the identification of the superior turbinate, this structure represents the medial wall of the posterior ethmoid. The natural ostium of the sphenoid sinus is at this point identified and widened through the dissection of the inferior portion of the superior turbinate in a tangential direction.

1.3. Transethmoido-Pterygoidal Corridor

The key point of this approach is the identification and the cauterization of two vascular structures: the sphenopalatine artery and the vidian artery. After a wide transethmoidal procedure, the approach continues with a partial resection of the middle turbinate and a wide posterior antrostomy. The subperiosteal dissection between the tail of inferior and middle turbinates allows to reach the origin of the sphenopalatine artery which is coagulated and then resected. The ablation of the posterior wall of the maxillary sinus permits the exposure of the contents of the pterygopalatine fossa and the consequent detection of the vidian canal with his coagulation.

At this point, a drilling of the base of the pterygoid and of the lateral part of basisphenoid is performed, in order to obtain a direct exposition of the lateral wall of the sphenoid sinus.

2. SPHENOID REGIONS

2.1. Sellar Region

The sellar region is delimited inferiorly by the sellar floor, superiorly by the superior intercavernous sinus and laterally by the cavernous sinus.

The paranasal direct corridor is the preferred approach to reach this region. A bilateral procedure is recommendable in order to obtain an adequate anatomical space to permit a 3- or 4-hands surgical technique and therefore an easier control of surgical complications, as intercavernous sinus bleeding.

The approach is usually extended anteriorly with the removal of 1 cm of the posterior part of the nasal septum and inferiorly, by a subperiosteal dissection, to the sphenoidal floor with the exposure of the T made by the union of the sphenoidal floor with the septal rostrum.

The transthemoidal corridor is preferred when the anatomical variations of the ethmoid sinus decrease the anatomical spaces, or in case of a necessary extension of the approach to the medial part of the cavernous sinus.

A partial removal of the middle turbinate could be required to obtain a correct exposition of the sphenoidal floor.

2.2. Lateral Parasellar Region

The lateral parasellar region is delimited medially by the medial part of the cavernous sinus, superiorly by the optic nerve, inferiorly by the vidian artery and laterally by the ethmoido-sphenoidal junction.

The surgical corridors to reach this region are the transthemoidal approach and the transthemoido-ptyergoidal approach; this choice depends on the pneumatization of the sphenoidal sinus and of his ptyergoidal recess.

In case of a non-pneumatized ptyergoidal recess, a transthemoidal corridor permits an adequate view of the lateral parasellar region. Instead, in the presence of a pneumatization of the ptyergoidal recess, a transthemoido-ptyergoidal corridor is preferred, in order to have a direct view of the infero-lateral part of the sphenoidal wall.

In both corridors, a posterior antrostomy, a wide ethmoidectomy with the exposition of the lamina papyracea and a direct exposure of the optical apex is required. The corridors are completed with a contralateral direct paraseptal approach and a removal of 2cm of the posterior part of the nasal septum.

2.3. Suprasellar Region

The suprasellar region is delimited inferiorly by the intercavernous sinus, laterally by the optic nerves and anteriorly by the ethmoido-planum junction.

In this region, a wide exposure is required in order to avoid complications in narrow anatomical spaces, in which many neuro-vascular structures are present.

The approach to this region requires a wide bilateral transtethmoidal corridor with the removal of the middle turbinate and a direct exposition of the ethmoido-planum junction and of the orbital apex bilaterally.

Before the widening of the sphenoidal ostium, a septal flap is created (in accord with the Hadad procedure) in order to reconstruct the skull base defect.

2.4. Clival Region

The clival region is delimited superiorly by the sellar floor, laterally by the carotid arteries, and inferiorly by the sphenoidal floor. The clival bone extends inferiorly in the rhinopharyngeal region.

The preferred corridor for the clival region is a bilateral direct parasseptal corridor, in this case a drilling of the sphenoidal floor between the two vidian artery (from the “T” to the clival region) is performed. A removal of 2 cm of the posterior part of the nasal septum (from the sphenoidal floor to the inferior choanal region) is required to adequately expose this region.

This corridor can be extended inferiorly with a rhinopharyngeal procedure, in order to expose the inferior clival region.

DISCUSSION

During last years, transnasal surgical approaches to the sphenoid sinus have been a great challenge for surgeons, because of the difficulty to adequately visualize a deep anatomical region and of the presence of important anatomical structures in contact with the sphenoidal walls [24, 25].

For many years, the most popular technique has been the sublabial transeptal approach, while other authors reported transtethmoidal and transpalatal routes [26, 27].

The experience in endoscopic sinus surgery (ESS) and anatomical endoscopic studies have permitted to extend such approaches from a simple opening of the sphenoid sinus (i.e. during transnasal procedure for inflammatory disease) to the endoscopic surgery of sphenoid sinus for the removal of benign tumors [3-6, 28-32]. Then, the transsphenoidal approaches were proposed for skull base surgery.

Since Jho in early 1990 described his experience in endoscopic approach to the sellar region, transsphenoidal surgery had a fast development [7, 9, 10, 11, 13, 33, 34]. Growing experiences in endoscopic sinus surgery and the cooperation between Otorhinolaryngologists and Neurosurgeons have led to an increasing interest in the transnasal endoscopic approaches to the middle skull base [9, 12, 15, 22, 23, 35].

Endoscopic skull base surgery started with mini-invasive targets, but nowadays is evolving, in order to obtain a good result with minimal access to permit an adequate resection, as with other conventional approaches [11, 14, 17, 19, 20, 36-38]. Evolving in skull base surgery required new closure strategies as multilayer closure and Hadad septal flap [16, 39-41].

In the last ten years, many classifications have been proposed, dividing the transnasal corridors according with the localization and of the extension of the pathology along the middle cranial base [11, 12, 18-22, 36-38]. However, there is a little consensus nowadays about the codification of the available approaches.

The best classification about surgical endoscopic transnasal corridors to the sphenoid sinus should consist of three types: transnasal, transethmoidal and transethmoido-pterygoidal.

The difference in the extension and in the widening of the corridor depends on the anatomical sphenoidal target. For this reason, the sphenoid sinus can be divided in four anatomical regions.

ABSTRACT

Cystic fibrosis (CF) is the most common life threatening autosomal recessive disorder affecting Caucasians. Molecular genetic mutations in the CF transmembrane conductance regulator (CFTR) gene alter function of CFTR protein, which leads to dysfunction in chloride channel on epithelial surface of exocrine glands. In the head and neck area, the pathology involves mostly paranasal sinuses starting from childhood. Chronic and recurrent rhinosinusitis with or without nasal polyposis and mucocoele of sinuses are the main disorders observed in CF patients. About 20-25% of these patients will require sinus surgery. Regarding surgical treatment, endoscopic sinus surgery (ESS) for management of paranasal sinus diseases in CF patients is undoubtedly a challenge for the surgeon. Moreover, evidence-based guidelines regarding the precise indications for surgery are currently lacking. Even if ESS is undeniably needed for management of sinonasal complications and can improve CF-related nasal symptoms, its role with regards to timing of surgery and consequent improvement of pulmonary function is not well described. Moreover, underlying medical issues such as acquired coagulopathies and advanced pulmonary disease, raise perioperative morbidity in these patients, with consequent and prolonged hospitalization. Indeed, the surgeon is often faced with distorted anatomy, due to anomalous development of nasal and paranasal structures or multiple revision operations. Therefore, multidisciplinary management of paranasal sinus disease in patients affected by CF is pivotal to achieve the correct surgical indication, prepare the patient for surgery, and address possible perioperative complications. The

authors describe the indications of ESS in CF patients, analyzing personal experience in the diagnosis and treatment of CF-related sinus disorders. Finally, data on follow-up after ESS, pulmonary function, and nutritional status will be presented.

INTRODUCTION

Cystic fibrosis (CF) is the most common life-threatening autosomal recessive genetic disease in the Caucasian population, and it is estimated that over 100,000 worldwide are affected. Thanks to advances in CF therapies, overall survival has increased. At present, more than 50% of those affected reach adulthood in USA, Europe, and Australia [1, 2].

CF is a multiorgan disease, with morbidity and mortality determined in the great majority of cases by progressive respiratory failure. As for the lower airways, at the basis of sinonasal manifestations there is a functional defect in the cystic fibrosis transmembrane conductance regulator (CFTR) gene, located on the long arm of chromosome 7. This gene encodes for a protein expressed on the epithelium of the airways where it works as a channel for chloride and bicarbonate and a regulator of other ion transport channels. The imbalance between ion transport channels (low Cl^- secretion, Na^+ hyper-reabsorption, reduced pH of airway surface liquid due to defective HCO_3^- secretion) lead to airway surface dehydration, causing thick and viscous secretions, chronic infections, and inflammation.

Generally, the clinician and the multidisciplinary team that deals with the treatment of the patient focus on lung disease, which, due to its characteristics, is the most fearsome manifestation. For this reason, the sinonasal manifestations of the disease are often underdiagnosed and not adequately treated. The patient himself, when the symptoms of the manifestation appear, may not give them an adequate relevance or do not have a wellness status as a comparison in case of an event that has always been present, and does not report symptoms to the clinician.

To date, the relationship between sinonasal manifestations and pulmonary disease has not been fully elucidated and there are several interesting theories that correlate aggravation of sinonasal status with a worsening of lung function, even after lung transplantation. However, it is certain that sinonasal symptomatology worsens the patient's quality of life, and therefore manifestations of the upper airways must be sought by the clinician through correct medical history, also considering the underestimations referred by the patient.

To date, considerable progress has been made in medical and surgical treatment of ENT pathologies in CF, and it is now possible to successfully treat such manifestations and improve the patient's quality of life.

In CF patients, a clinical picture of chronic/recurrent rhinosinusitis is generally observed and may be associated or not with nasal polyps. Moreover, a mucocoele of sinus can develop in some patients. Another characteristic of sinonasal involvement is hypoplasia/aplasia of some paranasal sinuses that is usually found at imaging.

PHYSIOPATHOLOGY

In the sinonasal epithelium there are two layers of liquid with different densities. A first fluid delineates and wets the eyelashes and is low in density, while the second is represented

by a layer of high-density, superficial mucus that has the function of trapping inhaled particles and transporting them through coordinated ciliary beat in the digestive tract [3]. This mechanism is called mucociliary clearance and is obviously an innate defense mechanism, guarding the upper (and inferior) airways.

The mechanisms of mucociliary clearance in the patient with CF are dysfunctional; due to altered anionic transport of mutated CFTR, there is a noticeable change in the viscoelastic properties of mucus, with increase in viscosity from 30 to 60 times above normal: the dense secretions obstruct the sinus ostia and create a state of hypoxia with edema and secondary ciliary dyskinesia; obviously this scenario facilitates bacterial colonization.

Bacteria release many substances that reduce the frequency of ciliary beats and help to create a chronic inflammatory state, promoting hyperplasia of mucus producing cells, along with squamous metaplasia and loss of cilia. Macroscopically, all these effects lead to stasis of infected mucus, inflammation, and alteration of gas exchange. The increase in PaCO₂ that is established also promotes edema and decreases mucus ciliary clearance [4].

In this complex pathogenic picture, anatomical anomalies, nasal polyposis, and mucocoeles can be found.

ALTERATION OF THE ANATOMY OF THE PARANASAL SINUSES

In recent years, the use of CT has been widely used pre-operatively to evaluate the anatomy of the sinonasal tract of patients with CF.

An often-observed feature is the lack of development or hypoplasia of the frontal and sphenoid sinuses. These sinuses develop mainly in the post-natal period and the pathogenic mechanisms underlying CF somehow hinder their normal development [5]. The same mechanisms are also responsible for reduced postnatal growth of the sinuses present at birth (maxillary and ethmoid).

It is hypothesized that chronic inflammatory status and reduced ventilation that reduce pneumatization are at the basis of this alteration. This hypothesis is supported by the fact that in the course of chronic otitis media there is no pneumatization of the mastoid.

Another possible finding is demineralization of bone walls, and in particular the medial wall of the maxillary sinus (which can also be medialized). It is also important to underline that a bone demineralization framework with medialization of the medial wall of the maxillary sinus is strongly suggestive for mucocoele.

NASAL POLYPOSIS

CF patients have a high incidence of nasal polyposis associated with chronic rhinosinusitis, which is present in up to 48% of patients [6]. On the contrary, in the child without CF nasal polyposis is an extremely rare phenomenon, and in fact the finding of nasal polyposis in the pediatric age must make the clinician evoke possible previously undiagnosed CF.

Nasal polyps in non-CF patients are benign proliferations of mucosal cells, characterized histologically by edema, hyperplasia of mucus producing cells of the epithelium, thickening

of the basal membrane, and the presence of numerous leucocytes, especially eosinophils (eosinophil-mediated inflammation).

CF related polyps have characteristics in common with those in the general population: focal edema, hyperplasia, atrophy or metaplasia of the epithelium, lamina propria which presents small vessels, and focal accumulations of inflammatory cells. Specific features of CF-related polyps are: thin basal membrane, lack of eosinophils, presence of neutrophil-mediated inflammation, acid mucin in the glands, continuous and fenestrated capillaries, and the presence of morphologically atypical plasma cells [7].

The physio-pathogenetic mechanisms underlying the formation of nasal polyps in CF remain unclear to date, as well as those of the healthy population. It is also not clear why some patients with polyposis have symptoms, while others remain asymptomatic.

MUCOCELE

Mucocele is a secreting mucus cyst, delineated by epithelium, which can localize and grow within a paranasal sinus with a concentric expansion [8]. It is a benign disorder, but with the accumulation of secretions it increases in size until the surrounding bone structures are moved and eroded. Thus, ocular and intracranial complications can arise. They can become infected, and in this case are referred to as mucopioceles.

Mucocele is believed to be formed due to obstruction of the sinus ostium. In the non-CF population it is typically a sinonasal adult disease, with onset generally in the third and fourth decades. The most frequently affected sinuses are the frontal and the ethmoid, and less frequently the sphenoid and maxillary [9]. It is a rare sinonasal disease in childhood, and in most cases is associated with CF. The mucocele is indeed part of the sinonasal complications typical of the disease [10], with a prevalence of up to 16% of patients with upper-airway disorders [11]. Some authors also suggest also that when the mucocele(s) is diagnosed in the first months of life, its formation had likely begun during intrauterine life [8].

The detection of mucocele in a child without a diagnosis of CF requires diagnostic investigation and a sweat test.

MICROBIOLOGY

The bacteria typically isolated from nasal material cultures of the patient with CF are *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Escherichia coli*, *Burkholderia cepacia*, *Acinetobacter spp*, *Stenotrophomonas maltophilia*, *Haemophilus influenzae*, *Streptococci*, and anaerobia.

The frequency of colonization of the lower airways by *Pseudomonas* in patients with chronic rhinosinusitis and polyposis is high; such colonization starts from the upper airways and then descends into the lower airways [12].

The association between cultures of the upper and the lower airways is verified, and has also demonstrated from a genotypical point of view: it is therefore correct to think that the paranasal sinuses can act as a reservoir for recurrent pulmonary infections in the disease [13]. It is therefore particularly important to improve the health of the sinuses as much as possible.

Hence the importance of considering and actively searching for the presence of sinonasal symptoms during patient interview. Moreover, for these reasons sinonasal surgery is indicated in preparation for lung transplantation.

CLINICAL MANIFESTATIONS

Symptomatology is due to chronic/recurrent rhinosinusitis associated with or not nasal polyposis. Patients can complain of nasal obstruction, anterior and posterior rhinorrhea, hyposmia/anosmia, headache, facial pain, and fever. Moreover, day and night oral respiration, snoring, decreased sleep quality, halitosis, changes in voice, and otalgia are other signs and symptoms that can be found.

When a mucocele is present, ocular signs and symptoms such as proptosis, epiphora, visual disturbances, and alterations of ocular motility may be observed. Mucocele can have a presentation without classical symptomatology and only with atypical manifestations. It is therefore essential not only to keep in mind the possibility of mucocele, but to seek it actively, especially in unclear and atypical situations.

DIAGNOSIS

If sinonasal manifestations are evident on history, the patient must be undergone careful ENT assessment, and, in particular, rhinoscopy under local anesthesia must be performed. At nasal endoscopy, it is possible to identify sinonasal anatomic anomalies (i.e., nasal septum deviation, concha bullosa, hypertrophy of the inferior turbinate), pathological nasal secretions, nasal polyps (Figure 1), and bulging of the medial wall of the maxillary sinus (Figure 2) and/or anterior wall of sphenoid suspicious for mucocele.

Figure 1. Nasal polyps (asterisks) associated with dense secretions completely obstructing the right nasal fossa.

Figure 2. Bulging of the medial wall of the left maxillary sinus (asterisk). The left middle turbinate is still visible (arrow).

The next diagnostic step is represented by imaging such as CT or MR of the paranasal sinuses. These radiologic studies allow overall assessment of the patient's sinonasal anatomy, identifying the sinonasal pathology and its extension.

Usually, mucocoele appears as a complete opacification of a single sinus. As the mucocoele expands, it remodels the local anatomy by slowly compressing surrounding structures, with consequent resorption of the neighboring bony walls (Figure 3).

Imaging (CT and/or MR) is needed to confirm diagnosis and identify bony changes and intraorbital (Figure 4) or intracranial extension of the expansive fluid-collection(s).

Figure 3. At coronal CT scan, a bilateral mucocoele (white asterisks) of the maxillary sinus associated with erosion of its medial wall is found.

Figure 4. At axial CT scan, a left ethmoidal mucocoele (white asterisk) is observed. Moreover, erosion of the lamina papyracea (white arrows) associated with displacement of the left medial rectus muscle is evident.

Cases of bilateral maxillary mucocoeles have been described, with CT showing a typical figure called “hourglass image,” which is formed by bilateral mucocoeles occluding nasal cavities [8].

In the literature, however, it is believed that the findings that can be visualized by imaging cannot be considered to be a reliable measure for outcomes after medical or surgical intervention. Some authors analyzed CT scans performed in patients with CF before and after surgery, graduating them with the Lund-Mackay (LM) score, and found that despite medical or surgical treatment there was no significant difference in the LM score of scans before and after intervention. Although CT is an important diagnostic step, performing multiple scans to monitor the disease is not useful and does not correlate with exacerbations of the disease or medical or surgical treatment. The study states that LM is a useful method of CT analysis, but does not provide adequate stratification for analysis of changes in opacification of the sinuses over time, especially in the case of partial opacification [14].

Although this study has not highlighted changes in CT, it underlines however that following intervention, improvements of symptomatology have been noted in the literature and hypothesizes that the benefit of surgery can be demonstrated by other parameters that analyze the quality of life [5, 15-16].

TREATMENT

In the last few decades, life expectancy of individuals suffering from cystic fibrosis (CF) has significantly improved, resulting in new medical perspectives for these patients. Life-saving treatments, indeed, have been progressively associated with interventions aimed to improve quality of life [17].

Since the sinonasal tract is involved in the majority of CF patients, otolaryngologists have a significant role in the multi-disciplinary management of these patients [17].

Management of chronic rhinosinusitis (CRS) in CF is challenging and is based on the combination of both medical and surgical therapy [18]. Appropriate medical therapy typically includes oral and/or intravenous antibiotics, topical and/or systemic steroids, and saline

irrigations [19-20]. In the literature, surgery is indicated when CRS does not respond to conservative maximal medical therapy and is performed in 20–60% of patients with CF [21-23]. This variable frequency of surgically treated patients mirrors the absence of consensus on indications and timing for surgery. In fact, no universally accepted guidelines for the surgical management of CRS in CF-patients are available.

Despite the large number of studies on this topic published during the last decade, the majority of these combined data from both adults and children, thus precluding firm conclusions on these exceedingly different groups of patients. Furthermore, only a few studies reached a good level of evidence [19-20].

The decision to indicate surgery is typically based on a combination of factors: clinical and/or radiological evidence of sinonasal disease (i.e., massive obstructive polyposis, diplopia, mucocele), patient-reported symptoms, sinusitis-related detriment of quality of life, overall health and nutrition status, occurrence of faltering growth, pulmonary conditions including recent pneumonia exacerbations and lung function parameters, patient personality, and patient-physician relationship [24, 25]. In the literature, there is conflicting evidence whether genotype correlates with severity of sinonasal disease and need for surgery. Some studies have demonstrated a relationship between homozygous F508 mutations and the degree of sinusitis, presence of polyps, and need for surgery [26-27]. Other studies, however, failed in showing an association between the homozygous F508 genotype and need for sinus surgery [17, 28].

CT and MRI definitely help in selecting patients who need surgery, depicting two clinical-radiological scenarios: 1) the most typical finding requiring surgery is the complete opacification of the nasal cavities due to massive polyposis and dense nasal secretions, with possible decalcification of the bony boundaries (i.e., ethmoidal roof, lamina papyracea); 2) other patients present with mucocele(s).

To date, 153 patients affected by CF are regularly followed at Unit of Cystic Fibrosis, Department of Pediatric, University of Brescia – Italy. Between December 2003 and May 2017, based on the aforementioned concepts, 43 (28%) of these patients underwent surgical treatment at Department of Pediatric Otorhinolaryngology, Spedali Civili di Brescia, Brescia - Italy. Thirty-seven and six children were operated for mucocele of paranasal sinus and CRS associated with massive nasal polyposis, respectively.

Surgical Notes

Historically, surgery consisted of open approaches to the sinuses (i.e., Caldwell-Luc procedure). Currently, endoscopic sinus surgery (ESS) is considered the mainstay of treatment of refractory inflammatory disease of the paranasal sinuses in CF patients. All our patients underwent such surgical conservative procedure. The key concept of ESS is widening the sinus ostia and removing obstructive nasal polyps to improve mucous drainage, provide proper ventilation of air spaces, and guarantee adequate penetration of topical medications (Figure 5).

Figure 5. A right wide middle antrostomy (white asterisk) is observed at endoscopic view. Mild adenoidal hypertrophy (white arrow) is present.

A number of general perils of ESS are emphasized when operating CF patients. The development of the paranasal sinuses can be incomplete, thus resulting in distorted and misleading anatomical configurations that can favor disorientation of the surgeon and subsequent complications. Continuous infections and multiple operations can subvert the sinonasal anatomy, further hindering the anatomical orientation during surgery. Thinning of the bony boundaries, typically involving the lamina papyracea and skull base, can facilitate the inadvertent injury of orbital and intracranial structures. Moreover, the bony lamellae of the nasoethmoidal complex are frequently resorbed, leading to the lack of anatomical landmarks that usually guide the surgeon during dissection. Furthermore, the active inflammatory process results in massive, dense secretions and increased bleeding. All the above-mentioned factors make ESS challenging and augment the risk of surgical complications, such as orbital injury and iatrogenic cerebrospinal fluid leak.

As an additional remark, underlying systemic alterations, such as acquired coagulopathies and advanced pulmonary disease, further raise the perioperative morbidity and lengthen hospitalization. Therefore, multidisciplinary management is of utmost importance not only to ensure the correct indications for surgery, but also to provide adequate preoperative preparation and minimize the possibility of perioperative complications. In particular, preoperative medical treatment with antibiotics and steroids associated with chest physiotherapy is mandatory to improve pulmonary function and nasal status. The surgical technique should also be customized in accordance with the physiopathology of CF: narrow and “minimalist” sinusotomies should be avoided in favor of wide and regular communications between sinuses and the nasal cavity; on the other hand, unnecessary mucosal stripping is strongly discouraged to minimize bone exposure and subsequent granulation. In line with this concept, a systematic review by Crockett et al. concluded that large maxillary antrostomies or modified medial maxillectomies provide significant improvement of the quality of life and sinus symptom scores, shorten hospitalization, and

reduce the need for antibiotics [29]. By virtue of the chronic nature of CF and the necessity to recurrently manage symptoms, less invasive procedures, such as simple polypectomy, have also been proposed. However, early recurrence of nasal polyps is more likely in patients undergoing polypectomy alone than in those undergoing polypectomy associated with functional sinus surgery (ethmoidectomy and antrostomy) [30]. Balloon catheter sinuplasty has recently been introduced for the treatment of CRS in pediatric patients. It is safe and effective and has the advantage of not requiring tissue removal, thus sparing most of the sinonasal mucosal lining [31]. Consequently, although no studies on the efficacy of balloon catheter sinuplasty in patients with CF are currently available, the procedure should be considered as a promising alternative to standard ESS.

As an additional refinement, when dealing with complex, recurrent cases, a neuronavigation system may be helpful to maintain anatomical orientation and avoid dreadful complications.

Outcomes

In view of the abovementioned criticisms, ESS can be considered as a safe procedure in patients with CF when performed by expert surgeons [32].

Patients who mainly benefit from surgery are those developing CRF due to both CF and anatomic variants compromising the spontaneous ventilation of sinuses, resulting in nasal edema/polypoidosis and drainage obstruction.

A recent review by Liang et al. reported that sinonasal symptoms (nasal obstruction, rhinorrhea, headaches, facial pain, and olfaction impairment), which were evaluated with validated questionnaires and/or subjective reports, invariably improve following sinus surgery [19]. Accordingly, improvement of CF-related CRS signs (polypoidosis, edema, mucopurulence, crusting, and/or scarring) was demonstrated in more than 50% of the included studies [19]. For instance, Virgin et al. reported significant improvement of both SNOT-22 and Lund-Kennedy score at one year after surgery [18]. Shatz et al. found a significant reduction of prescriptions for intravenous antibiotics for pneumonia after ESS [33]. However, this finding was not confirmed by other authors [34]. In fact, there is conflicting evidence whether ESS significantly modifies pulmonary outcomes in CF patients [19]. Kempainen and colleagues found no difference in number of days spent in hospital pre- and post-operatively [34]. Interestingly, patients who show the greatest sinonasal-related benefit from surgery are those with higher baseline pulmonary function: CF patients with a baseline %FEV1 above >70% predicted exhibited greater improvements in sinus symptoms after surgery than those undergoing medically alone [17].

Although several studies have recommended ESS in patients undergoing lung transplantation [33], this practice has largely lost popularity. Leung et al. demonstrated that lung allograft re-colonization occurs regardless of prior sinus surgery, concluding that prophylactic ESS is not beneficial [35].

Stringent and multidisciplinary follow-up is of paramount relevance to ensure adequate postoperative medical therapy and, ultimately, optimize surgical outcomes: ESS followed by intensive post-operative medical therapy (2 weeks of antibiotics, 6 months of nasal irrigations, and 12 months of topical nasal steroids) resulted in eradication of pathogenic sinonasal bacteria for up to 1 year [22].

It is important to highlight and counsel the patient's family that ESS does not provide a definitive cure for CF-related CRS: being a genetic, systemic disease, CF prevents normalization of sinonasal mucosa, though adequately managed.

Therefore, patients and their family should be made aware about the need to undergo multiple ESS procedures throughout their life; in fact, the revision rate for CF-related CRS ranges between 20% and 100% after a period of 2–4 years from primary surgery; this rate increases parallel to the severity of polyposis at primary presentation [36]. Intuitively, recurrence is particularly common when surgical intervention is incomplete and/or when adjunct treatment with antibiotics is inadequate.

Regarding our cohort of study, a recurrence of disease was observed in 6/6 (100%) patients who were operated for CRS associated with nasal polyposis, whereas no recurrence was found in 37 children operated for paranasal mucocele with a mean follow-up of 52 months after surgery. Finally, data about pulmonary function and nutritional status did not change after surgery (Table 1).

Table 1. Pulmonary function and nutritional status evaluated before and after ESS

	Before surgery (1 month)	After surgery (1 month)	p-value
FEV ₁ % predicted value	97,2	97,9	0,7
BMI (z-score)	-0,22	-0,27	0,19

ESS: endoscopic sinus surgery.

CONCLUSION

CF is a multisystem disease, frequently involving the sinonasal tract and manifesting with recurrent CRS with or not nasal polyposis and the tendency to develop paranasal mucocèles.

Evidence-based guidelines on the surgical management of CF-related CRS are lacking. Some evidence suggests that ESS could improve nasal symptoms and is strongly recommended to manage sinonasal complications. On the other hand, the timing of surgery and its role in improvement of pulmonary function remain a controversial issue.

When it occurs, mucocele of paranasal sinus is an absolute surgical indication and ESS is considered the surgical approach of choice.

However, ESS for CF-patients is challenging because of technical complexity and unfavorable underlying medical conditions that complicate perioperative medical management.

Consequently, a multidisciplinary approach to CF patients is the pivotal strategy to ensure the adequacy of surgical indication, optimize the general status of the patient, and manage possible perioperative complications.

Chapter 162

POSTOPERATIVE PANCREATIC FISTULA FOLLOWING DISTAL PANCREATECTOMY

Jennifer L. Olson, MD and Richard J. Bold*, MD

Division of Surgical Oncology, UC Davis Comprehensive Cancer Center,
Sacramento, CA, US

1. INTRODUCTION

Post-operative pancreatic fistula (POPF) is one of the most dreaded complications in any pancreatic operation given its associated morbidity and mortality. The amylase-rich fluid can cause inflammation, become infected, or cause serious bleeding from neighboring vasculature. POPF are at least as common after distal pancreatectomy than traditional pancreaticoduodenectomy, occurring in approximately 14-30% of all operations [1-3]. Unlike pancreaticoduodenectomy, there is no pancreatic ductal anastomosis at risk for leakage and disruption; it has been hypothesized that the intact sphincter of Oddi as well as the normal parenchymal texture accounts for the relatively high incidence of POPF following distal pancreatectomy. In a recent meta-analysis, the average rate of clinically relevant POPF was 15.5% with severe POPF requiring reoperation or resulting in organ failure and/or death was 1.3% [4].

2. DEFINITION

In 2005, a consensus definition was published by the International Study Group for Pancreatic Fistula (ISGPF) which has now been widely accepted [5]. Previously, definitions would be established for an individual study declaring a volume of amylase-rich output at a set time point. The 2005 consensus definition declares that “any measurable volume of drain fluid on or after postoperative day 3, with an amylase content greater than 3 times the upper normal serum value” is a POPF. The severity of the leak does not linearly correlate with the

* Corresponding Author's Email: rjbold@ucdavis.edu; Fax: (916) 703-5267.

increase in amylase. ISGPF then divided the POPF into 3 groups correlating with clinical consequences. The clinical parameters used to grade were overall clinical condition (well or ill appearing/bad), persistent drainage after 3 weeks, signs of infection, sepsis, readmission, and treatments including reoperation, parenteral nutrition, antibiotics, somatostatin analogues, and drain placement. Increased length of stay is included as a diversion from usual management [5].

In 2016, the guidelines were updated which downgraded a type A fistula to a “biochemical leak” instead of a POPF. The clinically relevant B and C fistulae criteria were further clarified. Interventions included an alteration of management to include percutaneous or endoscopic interventions for fluid collections or angiographic procedures for POPF-related bleeding. Grade C includes any POPF which require reoperation or that lead to organ failure defined by the need for re-intubation, hemodialysis, or inotropic agents [6].

Table 1. 2005 ISGPF POPF grading scale

Grade A	“Transient fistula” with no clinical impact lasting less than 3 weeks.
Grade B	Change in management required. Signs of infection without sepsis possible.
Grade C	Significant alteration in management required. Possible sepsis or critical illness. Possible reoperation required. Risk of death.

Table 2. 2016 ISGPF POPF grading scale

Biochemical Leak (No POPF)	Amylase-rich drainage lasting less than 3 weeks
Grade B	Change in management required. Signs of infection without sepsis possible.
Grade C	Significant alteration in management required. Possible sepsis and/or organ failure. Possible reoperation required. Risk of death.

While the standardized definition has aided comparative research, there is no diagnosis or ICD code for pancreatic fistula limiting database research to those maintained by individual centers. Distal pancreatectomy is performed less often than pancreaticoduodenectomy thus requiring more time for patient accrual. Also, the routine clinical pathways can vary greatly between hospitals and between surgeons, thus the simple requirement of a deviation from expected course can have a myriad of interpretations.

3. CLINICAL COURSE

POPF influences the clinical course in many ways. Length of stay (LOS) is increased as patients require ongoing drain management, additional imaging and procedures, and care for any other resultant complications. LOS for an uncomplicated distal pancreatectomy is impacted by the surgical approach and by institutional postoperative care pathways ranging from 5 to 12 days. When a patient experiences a grade B/C POPF, the median LOS increases to 19 days with a range of 7-69 days. Delayed gastric emptying is another common complication of pancreatic resection which can be exacerbated by a POPF [7, 8].

Undrained or inadequately drained pancreatic leaks can lead to critical consequences. The amylase-rich fluid can degrade the surrounding tissue including the splanchnic vessels

leading to major hemorrhage. When bacteria are introduced into the fluid collection, an intraabdominal abscess can lead to sepsis. In a retrospective analysis of 908 patients who underwent pancreatic resection, culture of the pancreatic fistula effluent revealed bacteria in 2/3 of the patients [9]. Organisms are almost always gram-negative rods or anaerobes which likely represent enteric bacterial translocation or seeding at the time of the operation [10]. Mortality attributed to complicated POPF are as high as 5% [9].

Oncologic outcomes are also influenced. Prolonged hospitalization and convalescence delay initiation of chemotherapy. Whether due to the delay or absence of adjuvant systemic therapy, or the impact of the complication on overall health status, recurrence-free survival for pancreatic adenocarcinoma is decreased after POPF [11].

4. PATIENT FACTORS

Many patient factors have been shown to predispose patients to POPF. Some are disputed such as increased BMI and malignancy [12-14]. Malignancy is reported to both increase and decrease the rate of POPF. It can alter the gland by enlarging the duct after an obstructive process facilitating identification for directed ligation. The pancreatic gland following neoadjuvant radiation is more fibrotic/firm and may be associated with a lower POPF. Pancreatic texture is widely accepted as a risk factor with a firm pancreas conferring a lower risk compared to a soft gland texture [3, 4]. Texture is a subjective assessment of soft and firm that cannot be determined prior to the operation and attempts to define texture radiographically have not been successful [15]. Poor nutritional status by different measures may increase POPF risk although it doesn't stand up to multivariable analysis and the difference of albumin between groups is subclinical [12, 16]. Knowledge of patient factors influencing POPF does not change patient selection but may influence preoperative counseling and post-operative decision making.

5. SURGICAL TECHNIQUES

5.1. Approach

Distal pancreatectomy can be performed open, laparoscopically, or robotically. The laparoscopic approach is popular given the advantages in hospitalization and recovery time for minimally invasive surgery. Given the absence of required anastomoses to create, the technical feasibility is within the scope for most pancreatic surgeons. Several studies have compared outcomes including POPF and have shown that the laparoscopic and robotic approach are safe. [15, 17-20].

5.2. Division

Division of the pancreas can be performed by scalpel, stapler, or energy device in an open surgery and stapler or energy device in a minimally invasive approach. There are many

studies comparing scalpel versus stapler without a clear advantage or disadvantage for any particular method. The comparisons within and across studies are often confounded by other technical aspects discussed later are not always controlled.

Stapler types include GIA and TA, single and multi-fire, and varying staple height from 1.0 to 2.5 mm with 2 to 6 rows of staples. A soft pancreas is considered more amenable to stapler division. Kawai et al., [21] studied the effect of pancreatic thickness on stapler efficacy finding 12 mm as a cutoff. Other groups adjust the staple height to accommodate the size and others exclude patients with a firm pancreas from the staple group. Compressing the gland before firing the stapler, closing the stapler slowly, and holding the device shut for a longer time have been suggested to lower the incidence of POPF [21-26].

Energy devices include unipolar and bipolar cautery, ultrasonic/harmonic scalpel, and a high-energy radiowave device which all coagulate, seal, and cut. The small trials for these instruments have shown them to be safe alternatives but without a clear influence on POPF rate or other advantage [21, 27-29].

5.3. Reinforcement

The pancreatic stump exposes the transected main pancreatic duct (PD) as well as smaller pancreatic ducts, all of which can contribute to a pancreatic leak or fistula. Many methods have been explored to reinforce the cut edge to decrease the number of POPF. Direct ligation with silk or slowly absorbing monofilament suture of the main pancreatic duct is often performed when the duct can be identified regardless of the method of pancreatic division [26]. PD ligation is one of the more consistent maneuvers which decreases POPF [7].

5.3.1. Oversewing

After scalpel division, the stump is often oversewn to compress and target the smaller ducts. Slowly absorbing monofilament is generally used with either individual or running stitches; mattress sutures are common [24, 26]. Although direct ligation of the transected duct would seem to reduce POPF and has been widely recommended, there is little comparative evidence to demonstrate its utility. However, limited data would suggest that the use of a non-absorbable suture should be avoided in closure of the pancreatic stump.

5.3.2. Fibrin

The coagulation factor fibrin can be employed in a number of ways to reinforce the transected pancreas although compelling evidence of its efficacy is lacking. It is available in multiple formulations allowing for spraying, injecting, and overlaying a patch including Tisseel (Baxter International Inc.), FloSeal (Baxter International Inc.), Evicel (Ethicon), TachoSil (Nycomed Pharma), Barillas P (CSL Behring), Thrombin-JMI (King Pharmaceuticals), Quixil (Omrix Biopharmaceuticals S. A. – Ethicon) [30].

Randomized controlled trials have been performed with favorable but not consistent results. In a small study, after scalpel division, duct ligation, and suture reinforcement, half of the patients received fibrin spray treatment which decreased the POPF rate from 40% to 15% [31]. Comparing application of fibrin spray after scalpel division and duct ligation either as a simple spray application versus when followed by suture compression forming a “fibrin

sandwich,” the sandwich group had a significant reduction in POPF (27% to 9%) [32]. Suc et al., [33] injected fibrin into the pancreatic duct which did not influence the POPF rate. TachoSil, an absorbable collagen fleece coated with fibrinogen and thrombin available in Europe was used in two RCTs buttressing either scalpel or stapler divided stumps and did not affect POPF rate [34, 35].

5.3.3. Mesh

Mesheres of various biochemical compositions can be secured over the cut end and some studies have shown promising results in decreasing POPF. Vicryl mesh, a polyglactin polymer available from Ethicon, was shown to be safe and effective with no grade B/C fistulae in a group of 26 patients after scalpel division [36]. Polyglycolic acid (PGA) mesh is a bioabsorbable synthetic polymer with cellulose-like structure which significantly decreased the rate of clinical fistulae after stapler division/reinforcement [37].

5.3.4. Intraductal Injection

Intraductal fibrin injection described above was designed to transiently obstruct the duct. Alternatively, a prolamine injection was administered in 51 patients who did not develop any POPF. The authors note that the substance was sometimes seen to extravasate from the cut edge or smaller ducts and hypothesized that the application was successful for addressing both the main and any branch ducts.

5.3.5. Biologic Patches

Biologic patches can be employed to reinforce the pancreatic stump and to provide a barrier between the pancreas and underlying vessels. Neighboring available structures that have been reported on are the omentum, round ligament of the liver, and a seromuscular jejunal layer. In a randomized controlled trial, there was minimal improvement in POPF after the round ligament was mobilized, introduced to the pancreatic stump through a defect created in the lesser omentum and then secured in place [38]. The jejunum was used as a patch by securing the stapler-divided, PD ligated stump to a loop of jejunum with interrupted seromuscular sutures after mobilization of the duodenojejunal flexure without opening the enteric lumen. There was no improvement in the POPF rate [39].

5.3.6. Pancreaticoenteric Anastomoses

Pancreaticoenteric anastomosis is sometimes employed during reoperation for pancreatic fistula so it was hypothesized that a preemptive anastomosis during the initial operation would be effective. Two randomized controlled trials have been performed that fail to show a significant decrease in POPF from a more standard approach. A pancreaticojejunostomy in which the first jejunal loop was used for an anastomosis and for a seromuscular parenchymal patch was trialed in 136 patients dividing the patients between anastomosis and stapler division/reinforcement [40]. Pancreaticogastrostomy in comparison to ultrasonic division with ductal ligation and suture reinforcement also did not show improvement [41].

5.4. Spleen-Preserving Distal Pancreatectomy

Distal pancreatectomy can be performed removing the spleen en bloc or leaving the spleen in situ to receive its blood supply via the short gastric arteries. In a retrospective study, Goh et al., found that 0/21 patients versus 14/117 experienced grade B/C POPF after a spleen-preserving procedure [42]. Other retrospective studies have shown no difference in the rate of fistula formation [14, 15].

5.5. Preoperative Endoscopic Adjuncts

Suspecting the intact Sphincter of Oddi to be a major contributor to increased pancreatic ductal pressure and resultant fistulization, preoperative endoscopic intervention has been trialed. These maneuvers have been directed at endoscopic measures to reduce the pressure gradient across the sphincter of Oddi and therefore reduce the pressure within the main pancreatic duct.

5.5.1. Botox Injection

Temporary paralysis of the Sphincter of Oddi could allow for ductal decompression during the postoperative period. A small German trial of preoperative Sphincter of Oddi Botox administration injected 100 units of Botox into the sphincter of Oddi 0-10 days before the operation. None of the 24 patients who were able to undergo their scheduled resection experienced a grade B/C fistula or any endoscopic intervention [43].

5.5.2. Stent Placement

In a randomized controlled trial for patients with planned distal pancreatectomy, 58 patients were divided into a control group compared to endoscopic stent placement into the pancreatic duct proximal to the pancreatic parenchymal transection site. The patients who underwent endoscopic stent placement had the stent placed at the time of the laparotomy with the endoscopist and surgeon working together to place the 5 or 7 Fr stent near but not within the planned stapled transection line. There were no endoscopic complications but also no reduction in POPF rate. The POPF that occurred in the intervention arm was attributed to stent migration [44].

6. PERIOPERATIVE DRAIN PLACEMENT

Drain placement and management varies widely between surgical practices. A drain is necessary to diagnose a biochemical leak or POPF in order to sample the amylase content. A biochemical leak, in fact, requires a surgical drain as any intervention to place a drain postoperatively would upgrade it to a grade B fistula.

6.1. Prophylactic Surgical Drainage

Surgical drains are often placed near the pancreatic stump. Closed suction is most often encountered, either a Jackson-Pratt or a Blake drain of 12 to 15 French. Some surgeons argue against routine drainage because a closed suction drain promotes fistulization, may introduce infection to a sterile fluid collection, increases one's leak rate without clinical consequence, and many patients still require additional drain placement. While the other side points out that a controlled, self-limiting pancreatic leak is better than an undrained collection with a delayed diagnosis and intervention.

A major randomized controlled trial in 2001 included both pancreaticoduodenectomy and distal pancreatectomy and showed that prophylactic surgical drainage did not improve the rate or grade of POPF. 40 of the total patients underwent distal pancreatectomy with 15 receiving a right and a left upper quadrant drain, although the positions were described in relation to the anastomoses of the pancreaticoduodenectomy patients. Subsequent analysis did not delineate the type of surgery but did show equivalence between the groups. There was no difference in in-hospital mortality, intraabdominal abscess, total number of complications, or even length of stay. 13% of patients with surgical drains still needed an interventional radiology procedure. The most common IR procedure was a drain placement for abscess, fluid collection, or hemorrhage, but also included retained drain and 2 inferior vena caval filter. They concluded that routine drain placement is not beneficial after pancreatic surgery [45].

More recently, a randomized controlled trial was conducted for just patients undergoing distal pancreatectomy acknowledging the different profile of complications. 344 patients were included divided into groups with and without routine drainage that were randomized for pancreatic texture and surgical approach. Primary outcome was any grade 2 or higher complication. There was no statistical difference between the groups for complications overall or clinically relevant pancreatic fistula. There were 2 deaths in the no drain group, both of which did develop a pancreatic fistula which was suggested to have contribute to their deaths by delay in drainage. Thus, their conclusion is that routine drainage is not absolutely necessary but due to the seriousness of the complications of no drainage, it is understandable if some surgeons continue to routinely place drains [46].

A more nontraditional suggestion was posited by Sugiyama et al., after a retrospective cohort study showed improved outcomes for drain fixation. Fixation of the drainage tip to nearby retroperitoneal tissue with a loose loop of absorbable suture decreased the number of additional postoperative procedures required and did not interfere with drain removal [47].

The available trials suggest that routine surgical drainage is not required for distal pancreatectomy. However, while trials may randomize for pancreatic texture, it has not been independently explored or discussed in a subgroup analysis.

7. POSTOPERATIVE MANAGEMENT

7.1. Postoperative Minimally Invasive Drain Placement

The first step in stable patients with undrained or inadequately drained peripancreatic fluid collections suspicious for POPF is drainage. Postoperatively, drains can be placed

minimally invasively by interventional radiology using CT or ultrasound guidance. In a retrospective analysis of 365 patients requiring IR drain placement after distal pancreatectomy, it was shown to be effective in the majority of cases and identified risk factors for the need for reoperation. The fluid collections were 2.3 to 16 cm, averaging 7.3 cm; presumably smaller collections did not require drainage and any critically ill patients requiring drainage were operatively drained. Drains were placed between post-operative days 2 and 120 (median of 23.5 days) and were in place for 3 to 220 days (median 40 days). 95% of the drains effectively drained the collection so that no reoperation was required. 40% needed readjustment or upsizing and the need for secondary manipulation was a risk factor in needing a reoperation. The authors emphasized the need for placement of the largest caliber of drain possible [10].

Any intervention or deviation from the expected clinical course, by definition, redefines a pancreatic leak to be a grade B or C fistula which can include the following treatment strategies in addition to drain placement.

7.2. Somatostatin Analogue

Somatostatin is a potent inhibitor of pancreatic secretions thus making it a promising target for drug therapy in the treatment of pancreatic leak. Several trials have been conducted assessing its use in routine postoperative management to prevent fistula formation. Its use as a treatment for diagnosed leaks is widely accepted although direct evidence of the effect on decreased drainage and any associated morbidity and length of stay is lacking. Administration is contraindicated in hyperglycemic patients as somatostatin also inhibits insulin. Side effects are most commonly gastrointestinal: nausea, vomiting, diarrhea, and abdominal pain [48].

The randomized controlled trials which address prophylactic use of octreotide center on pancreaticoduodenectomy with distal pancreatectomy as an exclusion criteria or a minor component of the whole. While some European studies showed some improvement in the POPF rate, two influential RCTs which argue against routine usage are from 1997 and 2000. In 1997, 120 patients undergoing pancreaticoduodenectomy for cancer were randomized between no octreotide and 150ug of subcutaneous octreotide every eight hours for the first five postoperative days. The octreotide group had a 12% rate of POPF vs 6% for the control group and the difference was not significant [49]. A similar negative result was seen in 2000 for pancreaticoduodenectomy patients receiving 250ug of octreotide versus placebo every eight hours for five days. Bilimoria et al., retrospectively examined patients who had distal pancreatectomy only for multiple factors including administration of prophylactic octreotide. 62 patients received 100ug to 300ug of octreotide given at the same interval. 18% of octreotide patients had a leak versus 30% of the control group but the difference was not statistically significant [7].

Octreotide was the first available somatostatin analogue. Vapreotide and Pasireotide are newer, longer-acting, more potent substitutes. In a randomized controlled trial of vapreotide given routinely after pancreatic resection every 12 hours for seven days, there was no decrease in POPF or related conditions. 52 of the 275 patients had undergone distal pancreatectomy [50]. Pasireotide is also dosed twice daily and was given for 7 days in the 2014 randomized placebo-controlled trial. Of the 539 pancreatic resection patients, 80 underwent distal pancreatectomy performed with a variety of division and reinforcement

techniques. 17% of the total patients receiving Pasireotide withdrew for nausea. Notably, there was a statistically significant decrease in POPF from 17% to 8%. Length of stay was also impacted; median LOS was one day shorter with administration of the drug [48]. Subsequent cost analysis questioned the impact of the improvement in rate and length of stay but ultimately found that despite the high cost of the drug, the cost savings for interventions and daily hospitalization supported the routine use of prophylactic Pasireotide [51].

7.3. Dietary Management

Classically, patients with suspected or confirmed pancreatic leaks would be made NPO in order to disrupt the gastropancreatic neurohormonal signaling. A more modern approach encourages oral nutrition whenever tolerated.

7.3.1. Oral Nutrition

In a small subgroup analysis within a retrospective study, patients with low output pancreatic fistulae were observed to spontaneously close with no improvement when receiving parenteral nutrition [1]. A randomized controlled trial comparing the treatment of POPF after any pancreatic resection with parenteral nutrition until resolution of the fistula versus enteral nutrition through an endoscopically nasojejunal tube showed an advantage for the enteral nutrition [52]. In a group of post-distal pancreatectomy patients with POPF, patients were randomized between parenteral nutrition and oral nutrition. Oral nutrition was well tolerated and was not associated with increased length of stay or other complications [53].

7.3.2. Fluid Restriction

When 330 patients undergoing pancreatic resection (96 distal pancreatectomy) were randomized between a liberal and restricted fluid management plan, there was no advantage or disadvantage between the two groups. The liberal arm delivered a standard maintenance fluid rate of 12ml/kg/hr with 250ml boluses for urine output below 0.5ml/kg/hr. The restricted arm delivered half of that rate with boluses for low urine below 0.25ml/kg/hr. There was no effect on POPF rate although there was a slight decrease in the rate of delayed gastric emptying. Two patients did develop chronic renal failure but the rate was equal between the study arms and was attributed to related POPF [54].

7.4. Endoscopic Intervention

Preoperative endoscopic Botox injection and stent placement were previously discussed. There is also a role for post-operative POPF management again suspecting the Sphincter of Oddi to be a major contributor to the increased intraductal pressure and fistulization. Goasguen et al reported overall success in treatment of prolonged POPF with endoscopic pancreatic sphincterotomy. Of the total 10 patients, 6 had undergone distal pancreatectomy and had a POPF diagnosed between postoperative day 3 and 21. 23 to 106 days after

diagnosis, endoscopic sphincterotomy with or without stent placement was performed with successful POPF resolution 1-12 days post procedure [55].

CONCLUSION

The risk of pancreatic fistula formation after distal pancreatectomy is considerable by any definition of POPF. Review of the literature for the lowest risk surgical technique is confounded by the inter-trial variability in all of the many factors. The inability to compare outcomes across hospitals limits the application of some research conclusions. While there is not a single tool or pharmacological agent that can substantially decrease the rate of POPF, early postoperative recognition in those patients at higher risk may limit the clinical consequence.

ABSTRACT

The minimally invasive sinus technique, (MIST) is different from minimally invasive sinus surgery. MIST implies a treatment philosophy and surgical model that is quite different from functional endoscopic sinus surgery (FESS).

The goals of this article are to discuss the origins of functional sinus surgery as it relates to the evolution of FESS and MIST, define MIST as a philosophy and surgical model, discuss treatment of surgical sinus disease, and challenge the rationale for our departure from Messerklinger's "functional" concepts into what will be referred to as "contemporary FESS." Many authors address the reduced revision rate (compared with FESS) following initial intervention with MIST, the potential to markedly reduce the rate of intranasal synechiae, and the reduction in immediate postoperative morbidity.

Keywords: minimally invasive, sinusitis, endoscopic sinus surgery

INTRODUCTION

Since its introduction in the mid-1980s, functional endoscopic sinus surgery (FESS) has become the standard surgical intervention for patients with chronic sinusitis refractory to medical therapy. In fact, FESS represented a targeted intervention, aimed at restoring normal sinus mucosal physiology as first described by Messerklinger in 1978 [1].

Through his endoscopic examination of the nose, Messerklinger describes a pattern of shifting light reflexes seen on the mucosal surface of the sinuses representing mucociliary movement that we now recognize as mucociliary transport or clearance. Using endoscopy in conjunction with time-lapse photography, he examined the direction of mucus movement and found that clearance was directed from the larger sinuses to their respective ostia. He also noted that contact between mucosal surfaces leads to disruption of mucociliary movement, thereby causing retention of secretions with subsequent obstruction of the subordinate maxillary, frontal, and anterior ethmoid sinuses. Furthermore, he recognized that contact is most likely to occur in the narrow transition spaces (i.e., ethmoidal infundibulum, hiatus semilunaris superior, and nasofrontal recess). Although contact may be a result of a number of causes, such as inflammation from environmental irritants, allergic rhinitis, viral infection, or anatomic distortions, these factors are most influential to the disruption of sinus physiology and development of sinusitis when they directly affect the aforementioned transition spaces. The theory that transition spaces represent the primary physiologic/anatomic bottleneck for the development of sinusitis is further supported by the high frequency with which the computerized tomography (CT) and clinical examination findings show inflammation limited to the maxillary, frontal, and anterior ethmoid sinuses; the posterior ethmoid and sphenoid sinuses do not drain into transition spaces.

Another critical realization in the development of FESS was that mucosal damage and mucociliary dysfunction is a reversible process. Before Messerklinger, most believed that mucosal damage found in chronic sinusitis was irreversible, and, therefore, procedures such as the Caldwell- Luc involved stripping of the sinus mucosa. In his clinical experience with more than 2,500 patients, Stammberger [2] showed that once the transition spaces are cleared of disease, the larger sinuses usually heal without being touched, even if mucosal damage seemed “almost irreversible”. Recent studies examining mucociliary clearance have shown that patients with chronic sinusitis have impaired mucociliary movement and that FESS is capable of correcting mucociliary dysfunction in these patients, thus showing the reversibility of disease [3-6]. To create optimal conditions for reversal of disease to occur, surgical intervention should avoid destruction of cilia and emphasize mucosal preservation.

Senior et al. [7] showed the favorable long-term results of FESS, with 98.4% of 72 patients having improvement compared with before surgery over an average 7.8-year follow-up period. Although there was a steep initial learning curve, many studies have since highlighted the relative paucity of complications associated with the procedure. In a study of 250 patients undergoing FESS, Levine [8] reported that minor complications developed in 8.3% of patients, while major complications developed in only 0.7%. In comparison, a study of 670 patients undergoing the Caldwell- Luc procedure, the previous gold standard intervention for chronic maxillary sinusitis, showed a 19% major complication rate [9]. Finally, because FESS is based on a minimally invasive approach compared with conventional surgeries, there were less overall postoperative discomfort and shorter hospital stays.

Although FESS initially established itself as a less invasive, more targeted, and more effective technique than its predecessors, conventional FESS has evolved beyond this description. Originally, proponents emphasized that FESS provides a conservative and effective surgical intervention, rarely requiring a middle meatal antrostomy or stripping of diseased nasal mucosa. However, over time, there has been a departure from these

conservative principles, with a tendency toward more aggressive intervention. As a result, surgeons have excessive freedoms in the nose, and sinus procedures are not standardized.

Although endoscopy offered a window for more precise visualization of nasal pathology, advances in other sinus instrumentation lagged. The original instruments used in FESS offered minimal precision, were associated with shear damage to normal mucosal tissue, and caused inadvertent stripping of mucus membranes. Technologic breakthroughs, coupled with a surgical model based on Messerklinger's principles [1], led to the next major advance in rhinology: powered instrumentation and the minimally invasive sinus technique (MIST).

DISCUSSION

Since its introduction in the literature in 1994 [9-10], MIST has grown in popularity worldwide. In the 2002, the first formal outcome study that compare MIST to FESS was published [11]. This study used the Chronic Sinusitis Survey (CSS) as the quality of life outcome instrument to assess improvement after MIST.

The outcome from MIST as measured by the CSS medication, CSS symptom, and CSS total subscales either equaled or surpassed those after FESS; the follow-up period for the MIST study was 23 months compared with 12 months of FESS and the surgical revision rate after MIST was 5.9% compared with an average of 10% after FESS. Furthermore, the results seen after MIST were consistent across the spectrum of disease severity (using CT grades I-IV), disproving the opinion that the procedure was only effective for minimal disease. These findings strongly support the recommendation that MIST be considered the initial surgical intervention for the treatment of chronic sinusitis. It strongly suggests that an excellent quality of life for chronic sinus sufferers could be achieved with minimal surgical manipulation of the nose and sinuses, it validates Messerklinger's transition space theory [1] and the reversibility of diseased nasal membranes, and it contradicts the rationale for the routine creation of a middle meatal antrostomy.

In fact, creation of a middle meatal antrostomy is occasionally required. Absolute indications include the biopsy of an antral mass, presence of ≥ 1 accessory ostia leading to maxillary recirculation, resection of a maxillary sinus fungal ball or inverted papilloma, and to allow for the application of topical medications or outpatient antral lavage in select cases. The concern with creation of a middle meatal antrostomy is not whether it works but whether it is necessary. Silva et al. [12] recently reported their study in which, for every surgical candidate with chronic rhinosinusitis, they performed a middle meatal antrostomy on one maxillary sinus but not the other. The results show no difference in the postoperative control of maxillary sinus symptoms or disease between the 2 sides. Thus, the potential risks of increased middle meatal scarring, interruption of mucociliary clearance and improper ostial function, development of maxillary recirculation by not including the natural ostia in the middle meatal antrostomy, and the likely need for revision maxillary surgery preclude the routine creation of a middle meatal antrostomy. Furthermore, authors conclude that the proper size of a middle meatal antrostomy can't be establish. Turbinate tissue is critical to proper nasal and sinus physiology. Routine resection of the middle turbinate often leads to edema and/or stenosis of the nasofrontal duct, and can produce compensatory glandular hypertrophy of the remaining nasal tissue. Powered shaving (i.e., thinning) of the lateral aspect of the

middle turbinate and powered resection of the lateral wall of concha bullosa, including the natural bullosa ostium, can each improve middle meatal airflow without incurring the risks associated with turbinate resection.

Another, less formal outcome study on MIST titled “Minimally Invasive Sinus Surgery in the Geriatric Patient” was published in 2001 [13]. The study used a geriatric population (ages 65 - 93 years) of 100 patients undergoing MIST for chronic sinusitis, to assess whether, because of their age, they had a higher potential for intraoperative or postoperative complications. The study patients also assessed subjectively the quality of life outcome after surgery, 6 months postoperatively. Of patients, 84% reported feeling significantly better, 10% somewhat better, and 6% unchanged. In comparison, another study of 119 patients with chronic sinusitis showed that 80.2% of patients had relief after FESS. Interestingly, 8 of 10 patients who reported feeling “somewhat better” after MIST, and 2 of 6 who had no improvement, had previously undergone aggressive FESS elsewhere.

The study also assessed whether there was any exacerbation of preexisting medical conditions or an increase in surgical morbidity after MIST. The 100 patients presented a spectrum of preexisting medical conditions, including hypertension, coronary disease, gastrointestinal disorders, diabetes, bronchitis and asthma, thyroid disorders, gout, stroke, renal disease, prostate disease, dysrhythmias, and others. Verifying the efficacy of MIST for the treatment of chronic sinusitis, the results highlight the fact that minimal medical/surgical morbidity is experienced by geriatric patients after MIST, making the procedure equally safe for the oldest and potentially most frail portion of the population.

A more recent article evaluated the efficacy of various middle meatal stents used during MIST [14]. Retention time for the Gelfilm stent was 5 days, whereas it was closer to 8 days for MeroGel, which is a statistically significant difference. Visible middle meatal synechiae on the right side (Gelfilm) developed in 4 patients, and none were seen on the left. The perioperative morbidity associated with the use of stents was negligible and not side specific. Mero- Gel appeared to be an excellent middle meatal spacer during sinus surgery. Compared with the literature, in which the rates of middle meatal synechiae vary from 27% to 4%, the overall synechia rate in this study was only 2% (0% for the MeroGel side).

A rationale has been provided for the aggressive ethmoidectomy now seen in contemporary FESS, however, to our knowledge, the basis for it remains unproven. It has been shown in both animal and human studies that osteitis of ethmoid [15, 16] serves as a nidus for recurrent infection or mucosal inflammation and, therefore, may be responsible for persistent/ recurrent disease after medical/surgical intervention. Thus, it is proposed that aggressive removal of all ethmoid sinus partitions will theoretically minimize the risk of recurrence.

Recent studies have shown that single-photon emission computed tomography bone scanning of the paranasal sinuses in patients with chronic sinusitis may be helpful in identifying foci of osteitis preoperatively [17]. These foci were correlated with histopathology of osteitis in 94% of cases examined. Therefore, CT absence of osteitis can address to MIST technique.

Regarding frontal sinus surgery, new mini-invasive approaches such as sinus balloon have been proposed. Currently the literature shows discordant results on this device so for our experience we recommend surgical approaches to this sinus with traditional surgery based on the principles proposed by Messerklinger to respect the sinus drainage paths [18]. About to

the sphenoid sinus, we consider mini-invasive to carve the rescue flap to be repositioned on the sphenotomy to prevent stenosis, iatrogenic mucocele and favor natural drainage [19].

POWERED ADENOIDECTOMY

Max M. April*, MD

Department of Otolaryngology, New York University/Langone Medical Center
New York, NY, US

ABSTRACT

Powered adenoidectomy was first described by Dr. Peter Koltai in 1997 [1]. This technique allows for constant suction and more precision in the removal of adenoid tissue.

Keywords: adenoidectomy, powered adenoidectomy, microdebrider adenoidectomy

INTRODUCTION

First performed in the mid 1990s, the initial powered adenoidectomy was performed with a bendable microdebrider blade. There were several issues, including frequent blade clogging due to the angle of the bend. The inner cannula would also get separated from the outer cannula making the blade unusable. The issues with those blades were improved with prebent standard blades. In addition, I designed a blade appropriately sized for most children (RADenoid blade 4mm opening and 11 cm length with a 40 degree curve which is manufactured by Medtronic, Figure 1A) and a larger one (4.5 mm opening, 13 cm in length with a 45 degree curve also manufactured by Medtronic, Figure 1B), intended for adolescents and young adults (my royalty agreement with Medtronic expired in 2010). More recently, Olympus has produced a similar blade for their Diego handpiece. (Figure 2)

Once mastered, powered adenoidectomy is a technique that improves visualization and accuracy. It has advantages over the previously used curettage and suction cautery methods.

METHODS

When powered adenoidectomy is performed, with or without tympanostomy tubes or other procedures such as frenulectomy (but usually not tonsillectomy), a laryngeal mask airway (LMA) may be used. In smaller children, a flexible LMA can be used depending on the anesthesiologist's experience. When using a flexible LMA, it is quite important to lubricate the tongue blade for easier manipulation when putting the child in the proper position (Figure 3). Often the LMA has to be repositioned slightly for an adequate airway. Care must be taken not to place the tongue blade handle at too sharp an angle onto the Mayo Stand (use the mouthgag with the right side open for a right handed surgeon) or it may cause a kink in the flexible LMA and reduce ventilation. Once the proper position is obtained with good ventilation (Figure 4), the hard and soft palate are both closely examined. The identification of a submucosal cleft palate is extremely important. The hard palate is palpated to confirm there is not a notch of the posterior portion. The soft palate is visualized with the surgeon's headlight to confirm the lack of a zona pellucida (mucosa without underlying muscle) in the midline. If there is a submucosal cleft, many otolaryngologists recommend that an adenoidectomy not be performed to prevent velopharyngeal incompetence (VPI). In this situation, a superior adenoidectomy can be considered [2]. The use of a microdebrider enhances the surgeon's ability to remove the superior portion of adenoid tissue to improve nasal obstruction and, for patients with ear symptomatology, remove adenoid tissue in the fossa of Rosenmuller. A less recognized potential cause of VPI after adenoidectomy is the short soft palate. Upon careful palpation (Figure 5), there are many more instances of a short soft palate than a submucosal cleft. Again, a powered adenoidectomy is an excellent method to remove most of the adenoid tissue, but be sure to leave an inferior ledge, which will improve postoperative palatal closure and lessen nasal escape.

After inspection, palpation, and choosing the plan of the specific adenoidectomy, drip 0.5 ml of oxymetazoline 0.05% (Figure 6) into each nasal passage. A minimum of instruments should be set up on the Mayo stand (Figure 7), including 2 red rubber catheters (8 French), 2 tonsil clamps, a mirror, antifog, and 2 tonsil sponges soaked with Afrin. Using Afrin prior to any other step may reduce blood loss and is known to improve nasal patency, especially in the Post-Anesthesia Care Unit (PACU). Tape the eyes, then place the head drape. Securing the head drape with tape avoids possible trauma from a towel clamp. A red rubber catheter (unless the patient is latex sensitive) is placed through each nostril to elevate the soft palate. The catheters are brought out through the oral cavity and clamped with a hemostat with the curve pointing up. The catheters are clamped to elevate the palate, but with little tension. If they are clamped tighter, there would be better exposure, but would produce more palatal swelling. With the clamp tip pointed up, the surgeon can intermittently retract the catheter with the ring finger when more exposure is needed (Figure 8). This technique is often helpful in smaller children and those with a relatively small oral cavity. The microdebrider blade allows the surgeon precise removal of exact tissue, but there is a learning curve. Because there is constant suction, there is a potential for damage to surrounding structures, especially the uvula, buccal mucosa, and lips. It is important to use the mirror, having first been dipped in antifog solution, to cover the opening (Figure 9) of the microdebrider blade both on entry and removal of the blade. The console was set at 1500 rpm, but now 2000 rpm is used (Figure 10) in oscillating mode. The oral stabilizer should have the opening on the side of the

surgeon's dominant hand. For right handed surgeons the opening of the mouthgag is on the right side. That enables a better angle for the microdebrider blade to get into the nasopharyngeal choana (Figure 11). The tongue blade selected should be the one that points the endotracheal tube or the LMA tube toward the anesthesiologist.

When ready to begin powered adenoidectomy, recognize the position the nasopharynx is in; this may vary depending on many factors. The angle of the nasopharynx often appears with the inferior most portion of the adenoid tissue higher than the superior aspect (Figure 12). That may promote deeper dissection with the blade in the infero-lateral portions of the nasopharynx. As that is where the blood supply emanates, dissection too deep in those areas produces much more bleeding, which in turn leads to more cauterization and then more pain. Be aware of that angle in every case and bring the debrider blade more superficial, removing only lymphoid tissue and not entering the underlying muscle. In smaller children, starting in the left choana, using care not to damage the torus tubarius, the adenoid tissue is removed in two passes from superior to inferior. In older children, a third pass (in the midline) is necessary.

Early in their powered adenoidectomy experience, surgeons will need to pack the nasopharynx with a tonsil sponge soaked in oxymetazoline, then wring it dry for a few minutes prior to obtaining hemostasis with the suction cautery. As surgeons improve their technique, there is less bleeding and many times packing is not necessary. Suction cautery is set on a low wattage—less than 20 watts. The low setting may reduce thermal damage to the eustachian tube. The foot pedal control for the suction cautery has several advantages, including reduction of surgeon fatigue and more effective cauterization with less powerful suction, when less of the suction port on the hand piece is covered. That cannot be accomplished with the hand controlled cautery.

When adenoidectomy is performed without tonsil surgery, the postoperative course is very predictable. Antibiotics are not prescribed unless there is an active infection. Halitosis is present for a week. Most children tolerate a normal diet the day of surgery. Most children can return to school and all activities the next day. Rarely, older children may complain of neck discomfort or younger children may not want to look up or to the side for a few days after surgery. Subluxation is always a consideration, especially in children with Down Syndrome. There is very little in our literature about this neck discomfort, which prompted a recent survey of *American Society of Pediatric Otolaryngology* (ASPO) members [3]. Our experience is that a few doses of NSAIDs remedy the discomfort. If there is a low grade fever, then an antibiotic is also prescribed.

More advanced considerations: Recurrence of adenoid tissue and the need for more than one adenoidectomy is often brought up by parents. Since we began performing adenoidectomy with a microdebrider, revision adenoidectomy has been very unusual. That being said, approximately once a month, a patient presents with nasal symptomatology after a previous adenoidectomy. It is often after a cautery adenoidectomy. It may be that cautery adenoidectomy is less effective in removing all the lymphoid tissue, especially with a large adenoid.

Figure 3. Oral Stabilizer (mouthgag) being placed with lubrication on the tongue blade to decrease the possibility of displacement of the Laryngeal Mask Airway (LMA).

Figure 4. This surgical image depicts the position of the flexible LMA having been pulled back after the tongue blade has been inserted and the oral stabilizer opened. This maneuver is the key to the procedure's success and requires excellent communication with the anesthesiologist. It is imperative to confirm that the distal end of the tongue blade does not create an acute angle of the flexible LMA, reducing the ventilation. Most cases require that the LMA be pulled back and that the Mayo stand not be raised too high as not to limit the airway.

Figure 5. This surgical image indicates how the surgeon should palpate the soft palate to confirm whether or not it reaches the posterior pharyngeal wall. If it does not reach that far, more of the inferior tissue is conserved to reduce postoperative nasal emission.

Figure 6. This surgical image demonstrates the application of topical oxymetazoline placed with an angiocatheter prior to the placement of the oral stabilizer to allow for nasal decongestion and improve nasopharyngeal hemostasis.

Figure 7. This photograph shows the surgical set up for adenoidectomy with only essential equipment. With less equipment used the overall cost for each case is reduced and the operating room can order more case carts, reducing the need for flash sterilization and improving instrument longevity. Note the position and angle of the antifog applicator (green-lower left) for ease of use; also note that the cloth towel is covering the metal Mayo stand. The endotracheal tube and extension tubing is routed above the drapes so accidental disruption is avoided.

Figure 8. Intraoperative photo showing how the temporary extra retraction of the red rubber catheter with the fourth finger produces improved visualization, especially superiorly in the choanal area without uvular swelling, which is worsened by continuous tight retraction of the soft palate.

Figure 9. An intraoperative example of how to use the mirror to cover the suction hole when entering and exiting the mouth to avoid trauma to surrounding anatomy such as the uvula, buccal mucosa, or tongue.

Figure 10. The console of microdebrider (Medtronic) set at 2000 RPM in oscillating mode with endoscrub function off.

Figure 11. This intraoperative photograph shows the commencement of powered adenoidectomy. Temporary retraction of the left red rubber catheter and the angle of the microdebrider (with open right side for right handed surgeon) starts in the left choana.

Figure 12. This intraoperative photograph indicates why it is imperative to appreciate the angle of the nasopharynx for each case. This angle is dependent on multiple variables, including the patient's age, tongue size, angle of the tongue blade, as well as the use of an endotracheal tube or LMA. Often the position of the inferior portion of the nasopharynx is higher than the choanal portion, as depicted by my external hand position. Care must be taken to debride lymphoid tissue more superficially when operating on the inferior portion of the adenoid, especially in the lateral aspect.

Figure 13. This photograph was taken 2 years after the powered adenoidectomy. Notice the healed smooth nasopharynx and structure emanating from the torus tubarius. There is no adenoid regrowth. The superior portion of the torus has a small notch and all the adenoid tissue had been removed from there.

Figure 14. This intraoperative photo shows the structure emanating from the left torus tubarius, which should not be mistaken for adenoid tissue.

The torus tubarius is not a perfectly straight structure. There is always a small notch behind the superior portion of the torus tubarius on both sides that has adenoid tissue. If that tissue is not removed, it may hypertrophy long after the surgery. This can be seen in the healed nasopharynx approximately 2 years after adenoidectomy (Figure 13). Also note in this postoperative photograph the complete removal of all adenoid tissue and the smooth, healed nasopharynx, which reduces the adherence of bacteria and biofilm and which may improve surgical results for rhinosinusitis and middle ear issues.

Another observation is there is often a structure seen emanating from the midportion of the torus (Figures 13 and 14). It is seen much more prominently in children having adenoidectomy for non otologic reasons. It may be a dilator of the eustachian tube and should not be mistaken for adenoid tissue.

Chapter 165

INTRACAPSULAR TONSILLECTOMY: MY SURGICAL APPROACH (MAX M. APRIL, MD, FAAP, FACS)

Max M. April*, MD

Department of Otolaryngology, New York University/Langone Medical Center
New York, NY, US

ABSTRACT

This chapter reviews the thought process that I have developed in my practice over the last 16 years. It will not include references and comparisons to the experience of others. It will describe how I evaluate patients, discuss options with parents, and perform intracapsular tonsillectomy, as well as my postoperative instructions.

Keywords: intracapsular tonsillectomy, partial tonsillectomy, tonsillotomy, tonsillectomy, pediatric sleep apnea

INTRODUCTION

When evaluating children with obstructive symptoms, perform the history first. Apnea or gasping for air, restless sleep, frequent awakenings, snoring, tiredness during the day, and enuresis should all be discussed. In addition, dysphasia for solids and speech articulation with emphasis on hyponasality should also be reviewed. There are many times when parents answer clearly and convincingly regarding the above symptomatology. There are other times when the answers are not so apparent. In those cases, I recommend that parents observe their child's sleep two hours after the child goes to sleep for at least one hour. Ask the parents to make video and audio of the worst episodes, then edit these to show only the times where

* Corresponding Author's Email: max.april@nyumc.org.

they are concerned before sharing them with the otolaryngologist; the editing will save a lot of time during your office hours.

Prior to 2000, during the risk/benefit discussion, there were many times when I would recommend a formal sleep study, a polysomnographic evaluation (PSG), to determine whether ET/A should be undertaken. When discussing a 2% chance of postoperative bleeding, possible dehydration, and missing school for up to 2 weeks, it was prudent to have objective evidence from a PSG as a comparison point. I rarely would operate without an abnormal PSG. Now that intracapsular tonsillectomy gives us very little chance of bleeding, as well as a quick return to normal activity/school, balanced with only a small chance of tonsil regrowth, the pro/con risk/benefit question takes on a different process. Is restless sleep and snoring an indication for surgical intervention? There have been many parents that have described Powered Intracapsular Tonsillectomy and Adenoidectomy (PITA) as life changing for their child. I suspect that many of these children may have “passed” a PSG, but in reality their upper airway obstruction and sleep disordered breathing was treated with PITA, and in fact, had a large impact on their development. I would like to be able to conduct a study where like groups are compared and both study and define neurocognitive changes after resolution of what was previously diagnosed as primary snoring (normal PSG). However, neurocognitive changes are extremely difficult to study and to compare, especially after surgical intervention.

Other potential indications for surgery such as infectious episodes including sinusitis, pharyngitis, non-streptococcal tonsillitis, and streptococcal tonsillitis are reviewed through the electronic medical record. Three diagnoses that virtually eliminate the possibility of PITA are periodic fever with aphthous stomatitis, pharyngitis and cervical adenitis (PFAPA), previous peritonsillar abscesses, and possibly pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS), although the role of tonsil surgery in PANDAS is very controversial.

In my experience, the physical exam is paramount in discussing which surgical procedure should be considered. I evaluate tonsil size in more than just two dimensions, which is represented by the standard 1+ to 4+ scale. There are exophytic tonsils and endophytic tonsils. In addition, the endoscopic evaluation of the tonsil length and anterior to posterior size is important. There are times when a transoral evaluation of tonsil size is very different than a nasopharyngeal endoscopic examination. Inferior tonsil hypertrophy may involve laryngeal obstruction that cannot be truly appreciated transorally. I like to think that a better scale to measure tonsil size would be one based on volume rather than one based on a two dimensional measurement. When there is a larger anterior/posterior dimension, swallowing difficulties and hyponasality are more affected. Parental observation of the upper airway endoscopy in the office is also extremely helpful in the surgical discussion (video X). If only one parent is present at the visit, I suggest that they video the endoscopy with their phone to show the other parent; one video is often worth a tremendous amount of dialogue.

Early in my career, I remember that almost all children undergoing ET had 4+ tonsils. If the tonsils were smaller than 4+ and the adenoid was large, then adenoidectomy alone was often the chosen option. More recently, there have been many patients that have 2-3+ tonsils and have abnormal sleep (video X). There are times I have evaluated a child for another reason, seen 4+ tonsils, and asked the parents if the child snores. The answer has at times been an emphatic “no.” My explanation is that there is a unique equation for each patient that adds up the anatomic airway (tonsils, adenoid, tongue, jaw position) and the physiologic

contributions (underlying muscle tone, medical issues, and medications) explaining whether there is obstruction manifested by snoring. With the low complication profile of PITA, perhaps the diagnosis of primary snoring should be addressed surgically thereby improving sleep for these children.

There are certain diagnoses that should only have an extracapsular tonsillectomy performed. These include periodic fever syndrome (PFAPA), previous peritonsillar abscesses, pediatric autoimmune neuro psychiatric disorders associated with streptococcal infections (PANDAS), and those where asymmetry and malignancy is a concern. I also may recommend extracapsular tonsillectomy for endophytic tonsils, cryptic debris, and tonsilliths, especially in adolescent patients, unless there are extenuating circumstances where bleeding is more than the usual concern (coagulopathies, platelet disorders, or patients who are Jehovah's witnesses) or they are patients who use their voices professionally and scarring is more than the usual concern.

INTRACAPSULAR TONSILLECTOMY TECHNIQUE

Beginning Technique

After completion of the adenoidectomy (see Chapter 164), approach the right tonsil with the curved microdebrider blade (irrigation of the blade is not necessary). The photographs presented will be either from a 3 year old boy (Figure 1) with obstructive sleep apnea (witnessed apnea and awakening nightly) or a 5 year old girl (Figure 2) with recurrent streptococcal tonsillitis and snoring (her parents chose PITA because of her underlying neurologic issues).

For the first 10 years of intracapsular tonsillectomy, the microdebrider was set to 1500 RPM, and for the last 6 years, it has been set at 2000 RPM. It is extremely important that the uninitiated surgeon be aware how much potential damage the microdebrider can cause if absolute precautions are not adhered to. When one observes instructors or video procedures, the use of the microdebrider appears to be simple, but that is the result of the surgeon's experience. Mastering the hand, foot, and eye coordination takes time. It is imperative that surgeons focus their most heightened awareness while performing the surgery because these blades are extremely sharp and any break in concentration can produce unintended damage.

After setting the microdebrider speed, the oral stabilizer is used, and the tongue blade size chosen. Usually, I recommend using the smaller tongue blade (how often would a size 2.5 work better?) to decrease the trauma between the tongue blade and the mandible (Figure 3). Upon entry into the oral cavity, the opening of the blade should be covered with the Hurd elevator. The coated Hurd elevator is used to retract the uvula superiorly (Figure 4), which exposes the most superior aspect of the tonsil. The coated Hurd protects the patient from thermal burns from transmission through a non-coated instrument. The microdebrider is used to engage the most superior aspect (Figure 5), and the dissection is carried from superior to inferior. The best approach is to identify the proper level of dissection at the most superior level (video X). The difference in retraction can be seen in the example of the 5 year old in Figure 6, where the retraction is not sufficient and in Figure 7, where there is more superior retraction, which allows the dissection to begin in the proper plane. Using the ipsilateral hand

for the same size tonsil is safer because the anterior tonsillar pillar prevents the blade from removing too much tissue. It is a more conservative resection, but does take more time to perform.

The initial surgery I performed in my beginning experience involved taking the tonsil tissue to the level of the anterior and posterior tonsillar pillar. This process removed between 75 and 80 percent of most tonsils and improved the airway and the obstruction. Once surgeons acquire more experience, they can perform deeper dissections and remove more of the tonsil tissue.

Once the superior aspect of the tonsil has been addressed, the Hurd elevator is used in several different ways. It can be used to retract the most posterior tonsil tissue off the posterior pharyngeal wall to allow easier removal and prevent injury to the posterior pharyngeal wall. It can also be used to retract the inferior most tonsil tissue away from the base of tongue to facilitate resection (Figure 8). The anterior tonsillar pillar can also be retracted with the elevator to further the anterior tonsil dissection. The tonsil tissue is cauterized with a suction cautery (foot pedal controlled) on the most inferior 3/4 of the fossa. The superior 1/4 is not cauterized until after the red rubber catheters are removed (after obtaining hemostasis in the nasopharynx) because there is more space with the catheters out (Figure 9) and less opportunity to produce thermal damage to the mucosa. Using a foot pedal controlled suction cautery (15-20 watts) is quite helpful because one can suction with the hole open when cauterizing superiorly. If using the finger controlled suction cautery (holding the cautery button down and covering the suction port), one must use extreme care not to accidentally cauterize the uvula, which would cause increased pain, and when the uvula swells, more trouble breathing and swallowing in the postoperative period.

After the lower portion of the right tonsil is cauterized, use the debrider for the left tonsil. When inexperienced, the ipsilateral hand should hold the debrider of the tonsil that is being resected. Using the ipsilateral hand prevents going too deep and potentially through the capsule, which would increase pain and potential bleeding. When removing the debrider blade, confirm that your foot is not on the pedal and that the Hurd is used to cover the opening so the uvula is not injured. Always watch with extreme vigilance until the debrider has been completely removed from the oral cavity so the buccal mucosa or lip do not become collateral damage. Following this step, cauterize the lower portion of the tonsil. Remove the tonsil sponges from the nasopharynx and cauterize the adenoid bed. Remove the red rubber catheters (video X) because the exposure is much better without them retracting the soft palate and pulling the tonsil pillars closer, then cauterize the superior portion of the tonsil fossa (Figure 10). It is important to concentrate on the superior portion, especially with the cautery because that is the most common area of "recurrent" tonsil tissue after PITA. The handheld cautery is very useful, especially in a surgeon's early experience to "get" tissue that may have not been debrided. Spending more time with the cautery on that tissue will electrodissect it. It is important to make the tonsillar fossa as smooth as possible when finished. Use the cautery for even more removal of uneven areas, which are potential areas of biofilm adherence, and in turn could promote tonsil regrowth. The best analogy is the goal of mastoidectomy, to make the cavity as smooth as possible. The tongue blade is let down one notch and iced saline is used to irrigate the oral cavity and the nasopharynx.

Early on, we noticed that children recovering from PITA complained about tongue discomfort or that their tongue was cut. It was a new complaint, one rarely seen after ET. Most likely the reason is that there is less tonsil pain so now the patients notice the tongue

pain. One maneuver that has helped reduce the tongue pain is using iced saline irrigation, and then after the mouthgag is removed, the tongue is massaged with an iced saline soaked gauze. I used the above technique for the first few years of my intracapsular tonsillectomy experience, only for patients with obstructive symptomatology. For early adapters of IT, I suggest using this technique until surgeons are completely comfortable with this procedure.

Figure 1. A 3 year old boy with 4+ thick exophytic tonsils is shown. The surgeon is placing the oral stabilizer.

Figure 2. A 5 year old girl with recurrent tonsillitis and right exophytic and left endophytic tonsils.

Figure 3. A 3 year old with size 2 tongue blade in place is shown in this endoscopic image.

Figure 4. This endoscopic image shows the beginning of the procedure, with retraction of the soft palate with a coated Hurd elevator.

Figure 5. This endoscopic image shows more retraction of the soft palate to allow engagement of the most superior portion of the tonsil.

Figure 6. This photo shows not enough retraction superiorly. If the dissection started at this point, less tonsil tissue is removed.

Figure 7. With more superior retraction, the deeper portion of the tonsil can be engaged with the debrider blade.

Figure 8. The coated Hurd elevator can be used to bring the inferior tonsil tissue away from the base of the tongue to reduce injury.

Figure 9. Cautery of the superior portion of the tonsil fossa is more effective without the red rubber catheters in place, thereby giving more exposure to the area.

Figure 10. Completion of the procedure in the 3 year old.

More Advanced Technique

With more experience and the inclusion of children with infectious indications, several modifications were made for PITA. For a right handed surgeon, the right tonsil is addressed, but the dissection is continued deeper with different retraction maneuvers (video X), including pushing the posterior pillar more anteriorly, which in turn pushes more tonsil tissue to be debried. Retracting the anterior pillar more also allows more access for increased removal of tissue. Another change was that the left tonsil was then debried with the Hurd elevator placed behind the posterior pillar (video X) , creating a tourniquet effect (Figure 11). Not only does this technique cause less bleeding, but using the contralateral hand is a more aggressive removal of tissue (Figure 12). It is much easier to go too deep with this technique, and there is a higher learning curve. Because the dissection of the left tonsil is quicker, one does not need to cauterize in between debrieding the two tonsils. Without changing from debriider to cautery twice, the procedure is less time consuming. There are patients with cryptic debris or tonsilliths that can make the shaving much more challenging, often in the superior pole area. These crypts must be closely followed (Figure 13) and all of the debris removed or there is a much higher likelihood of tonsil regrowth. In patients with infectious indications for surgery, a more deep dissection can be considered: this is known as extended IT. Extended IT is my procedure of choice, especially in voice professionals (Figure 14) or in children that have underlying muscular issues where ET may have too much negative impact on speech, voice, and swallowing. These patients often have more discomfort and certainly more otalgia, both of which should be included in the preoperative discussion. When healed, they still have their anterior and posterior tonsillar pillars, as well as the preoperative pharyngeal height. Please review the multiple surgical videos of IT (videos X-X).

Figure 11. The beginning retraction of the left tonsil with the Hurd elevator.

Figure 12. More retraction is at risk. With the use of the right hand debriding the left tonsil, the dissection is quicker and more aggressive.

Figure 13. In patients with endophytic or cryptic tonsils, the soft palate retraction is needed for deeper dissection and to follow the cryptic debris.

Figure 14. An example of large cryptic tonsils in a Broadway performer. PITA was chosen despite the cryptic tonsils, to reduce impact on her voice.

POSTOPERATIVE CARE

Initially, narcotics were prescribed after IT. After several years of parents saying that their child never used the prescription, that practice was changed. Since 2010, a narcotic prescription is not given after the surgery, with very few exceptions. Acetaminophen and NSAIDs are used as needed in the postoperative period, including the PACU, if necessary. It is still recommended not to use NSAIDs for 1 week prior to surgery, especially not for the 48 hours prior to surgery. Whereas ET would be cancelled if there were NSAIDs given in the 2 days prior to surgery, there have been instances when IT was performed with some hesitation, but without bleeding (as of yet). There are some children that take no medication for pain postoperatively. Some patients are given acetaminophen (10 mg/kg) once or twice a day and some children need medication more often. Older patients are given medication if requested for pain, while it is recommended to give younger children either acetaminophen or NSAIDs, if they are not eating or drinking well, even if they are not complaining of pain. The worst case scenario, which rarely occurs, is using acetaminophen alternating with NSAIDs (10 mg/kg).

Antibiotics are not routinely used intraoperatively or postoperatively. The exceptions include a purulent rhinosinusitis or tonsillitis at the time of surgery. Halitosis is almost universal (much more common since not using antibiotics as the American Academy of Otolaryngology Head and Neck Surgery (AAO-HNS) recommended in 2011). This halitosis usually resolves in a week. Increased fluid intake helps somewhat. If neck pain develops a few days after surgery, NSAIDs are recommended (see Chapter 164).

Postoperative dietary restrictions are few. For the first few days, the child should not eat anything hard or scratchy, such as pizza or pretzels. Eating almost anything else is not a concern. Many parents describe stopping at the child's favorite food establishment for chicken nuggets, burgers, or pasta on the way home from the hospital.

Activity and return to school are variable and up to parental decision. Some children return to school the next day, but the usual time period is 2-4 days after surgery. There are no

physical activity restrictions for younger children, but older patients should not participate in organized sports for one week.

One last topic that must be addressed is what happens if completion tonsillectomy is necessary in the future. The reasons for this may include a peritonsillar abscess (certainly a recurrent one) after PITA or continued streptococcal infections or tonsilliths. I have performed 3 completion tonsillectomies after PITA. All three procedures were very straight forward and there was no excessive bleeding or pain.

Chapter 166

INTRACAPSULAR TONSILLECTOMY: MY SURGICAL APPROACH (ROBERT F. WARD, MD, FACS)

Robert F. Ward, MD

Department of Otolaryngology, New York University/Langone Medical Center,
New York, NY, US

ABSTRACT

This chapter, like the next one by Dr. John Bent, will highlight the differences and similarities between my approach to intracapsular tonsillectomy and adenoidectomy relative to what has been described by Dr. Max April in chapter 165.

Keywords: intracapsular tonsillectomy, partial tonsillectomy

INTRODUCTION

I am in agreement with Dr. Bent (see Chapter 167) that intracapsular tonsillectomy has been one of the biggest advances in pediatric otolaryngology during my career. It has certainly advanced patient safety and demonstrated equal efficacy to extracapsular tonsillectomy. The main risk in tonsillectomy has always been postoperative hemorrhage. With the use of the intracapsular tonsillectomy technique, postoperative hemorrhage has become an insignificant concern. Only one of my patients has required follow-up for a post tonsillectomy bleeding episode and this turned out to be the result of an undiagnosed von Willebrand's disorder. Even in this case, the bleeding was not truly life-threatening, but rather recurrent and of low impact.

As has been mentioned by Dr. April, I do discuss the two types of tonsillectomy with all families before their child's surgery. Very frequently the parents indicate that they have been misinformed about intracapsular tonsillectomy and believe the procedure is associated with more bleeding than with extracapsular tonsillectomy. Many parents are also concerned that

after intracapsular tonsillectomy there is the risk for the tonsils to regrow very frequently. This certainly has not been our experience [1]. In my experience, the development of tonsil regrowth to the point where the child experiences obstructive symptoms again is less than 1%. Likewise, this tends to occur in the very young children. In our paper [1], we did not see any significant regrowth in children over the age of five when the ITA was performed.

I agree with Dr. April that there are certain diagnostic situations that indicate only an extracapsular tonsillectomy should be performed. These include: periodic fever syndrome, pediatric autoimmune neuropsychiatric disorders associated with strep infections, and cases of pediatric tonsillar malignancies.

However, I do think that over time we will see more and more intracapsular tonsillectomies performed for recurrent streptococcal infections. While the literature includes only a few papers suggesting that the efficacy of intracapsular tonsillectomy is equal to that of extracapsular tonsillectomy for the control of recurrent tonsillitis, anecdotally, I have performed over 40 intracapsular tonsillectomies for the treatment of recurrent strep infections. Of these, I have taken one patient who initially underwent a coblation tonsillotomy for recurrent strep infections back to the operating room for a completion tonsillectomy.

I agree with Dr. Bent that Powered Intracapsular Tonsillectomy and Adenoidectomy (PITA) seems to be more effective than extracapsular tonsillectomy in treating hypertrophic tonsils. However, I still favor Extracapsular Tonsillectomy and Adenoidectomy (ETA) for small, endophytic, and contracted tonsils. For larger endophytic tonsils, I tend to perform an Intracapsular Tonsillectomy and Adenoidectomy (ITA). These cases are a bit more challenging than the exophytic tonsillar tissue, but still can be done effectively.

PREOPERATIVE CONSIDERATIONS

I echo the preoperative considerations suggested by Dr. Bent. I would like to emphasize the specific issue regarding children who demonstrate abnormal speech patterns and the ensuing consideration of tonsillectomy and adenoidectomy. These particular children do require preoperative speech evaluation. If there is any anatomical suggestion of palatal dysfunction, I would strongly recommend PITA. It has been demonstrated that a tonsillectomy and adenoidectomy are not contraindicated for children with hypernasal speech or with a bifid uvula.

Dr. April's observation regarding the potential for lateral pharyngeal wall scarring seen after ETA may worsen not only sleep issues, but also the hypernasal speech issues. This type of scarring is never seen after ITA. Likewise, if there are hypertrophic tonsils noted in a patient who is to undergo a posterior pharyngeal flap for velopharyngeal insufficiency, we perform an IT concurrently with the posterior pharyngeal flap. We presented our results for IT and concomitant posterior pharyngeal flap for velopharyngeal dysfunction at The Society for Ear, Nose and Throat Advances in Children (SENTAC). In 12 patients we had no problems in performing the two procedures together. The risk of scarring of the palatopharyngeus and palatoglossus muscles is much less with IT than with ET.

INTRACAPSULAR TONSILLECTOMY TECHNIQUE

Before beginning intracapsular tonsillectomy, I perform the adenoidectomy with a curved microdebrider. There are times that the tonsils are so enlarged that the nasopharynx cannot be adequately accessed with a mirror; therefore, I will perform the IT before the adenoidectomy. For the first several years, starting in 2000, I performed IT, patients were orally intubated for the combination of adenoidectomy and tonsillectomy. In the last few years, several of our anesthesiologists have favored a laryngeal mask airway (LMA) for adenoidectomy. I think that this is also possible to use LMA in many cases for intracapsular tonsillectomy. As has been mentioned by Dr. April, I favor using a smaller tongue blade for IT. When using a LMA, I believe that for the stabilization and correct fitting of the laryngeal mask airway, it is necessary to use a larger tongue blade.

In keeping with the AAO-HNS guidelines we typically give intraoperative steroids during the course of IT. Intravenous antibiotics are not routinely given. As Dr. Bent has discussed, we occasionally will use postoperative antibiotics in a child that shows evidence of mucopurulent secretions emanating from the nasopharynx or when mucopurulent secretions are found in the oral endotracheal tube at the end of the procedure.

I start the procedure by elevating the soft palate with a red rubber catheter. I typically place the catheter in the right nostril and try to elevate and "hide" the uvula with the single catheter. It is been my experience that if two catheters are used, the uvula is left protruding in the midline and is at a higher risk for injury with the debrider blade.

I favor using the microdebrider over the coblator or other methods. This tool allows for cleaner removal of the lymphoid tissue without generating any significant thermal injury to the surrounding tissues. I began performing PITA with the debrider set at 1500 RPMs. Throughout my experience, I have continued to use this setting, even though I've experimented with slightly higher rpms. It is important to have the debrider blade set on the oscillating setting. As will be discussed by Dr. Bent, the slower speed does allow more tissue to be suctioned into the blade and transected than at higher RPMs. In my experience, the need for powerful suction on the debrider is extremely important. Again, this allows for more of the tissue to be suctioned into the blade and seems to cause less bleeding. Being right-handed, I start with the left tonsil for the same reason that most right-handed surgeons perform septoplasty from the left nostril. It is generally easier to operate with a surgical instrument directed towards the surgeon rather than away. This also places the hand in a more natural pronated position. For the right-handed surgeon, removing the right tonsil first places the hand in a less desirable supinated position.

Before any cauterization, I attempt to shave both tonsils. I follow Dr. April's pointers in using the hurd elevator to help deliver the tonsillar tissue. I also strongly agree that recurrent tonsil growth most commonly happens at the superior pole region. In particular, I spend as much time as necessary trying to clear as much of the superior tonsillar tissue as possible. I agree with Dr. April on the concept of the extended PITA, particularly when indications for surgery involve recurrent infections, cryptic tonsils, or tonsil stones.

After intracapsular removal of the tonsils, I usually place cold wet gauze in the area of both tonsils. This seems to help to decrease any oozing from the tonsillar beds. I then use the suction cautery on a setting of 25 Watts. I do not distinguish any difference in cauterization from the inferior or superior poles. I do not think that the extent of cauterization on the

remaining lymphoid tissue impacts on the degree of postoperative pain. I irrigate the nasopharyngeal and tonsil beds copiously prior to removing the mouth gag. I have found that reopening the mouth gag is not necessary.

POSTOPERATIVE CARE

I follow the postoperative care instructions that have been described by Drs. April and Bent. I recommend a combination of acetaminophen and NSAIDs. I do not suggest any dietary restrictions. I allow the children to eat anything they are comfortable with. The level of activity and the return to school is variable, as has been suggested. In the younger children, I do not suggest any restrictions of activity. In the older children, I ask that they refrain from organized physical activity for one week.

I typically see patients 1 to 2 weeks after surgery. I agree with Dr. Bent that routine follow-up is perhaps unnecessary. In those children with unusual findings in the operating room or who have preoperative documented obstructive sleep apnea, I do believe that they should be seen postoperatively and may need a follow-up sleep study performed.

Chapter 167

INTRACAPSULAR TONSILLECTOMY: MY SURGICAL APPROACH (JOHN P. BENT, MD)

John P. Bent*, MD

Department of Otolaryngology-Head & Neck Surgery,
Pediatrics Albert Einstein Medical College/Children's Hospital at Montefiore
Bronx, NY, US

ABSTRACT

This chapter highlights the differences between my approach to intracapsular tonsillectomy and adenoidectomy (ITA) relative to what Dr. April described in Chapter 165.

Keywords: intracapsular tonsillectomy, partial tonsillectomy, tonsillotomy

INTRODUCTION

Among surgeons who are willing to consider performing ITA or ETA, most tend to prefer one technique over the other. Given the right circumstances, I strongly prefer ITA. ITA represents one of the biggest advances in pediatric otolaryngology, during my career, in terms of advancing patient outcomes and safety. I have completed over 2,000 ITAs and have never taken a patient back to surgery for hemorrhage. The marked reduction in pain essentially obviates the need for narcotics. By taking postoperative exsanguination and death from narcotic-induced respiratory depression “off the table,” ITA eliminates the two main causes of dreaded post-tonsil mortality.

Undoubtedly, my bias influences my evaluation, and the consent process, but I try to keep all patient encounters transparent and objective. After the discussion of potential risks, benefits, and alternatives, nearly all families to whom I recommend ITA accept my

* Corresponding Author's Email: jbent@montefiore.org.

recommendation. If they choose ETA despite my recommendation, I ask them why. Often their answer reflects a lack of understanding, for instance they may say “I don't want my child to go back under anesthesia if the tonsil regrows,” not appreciating that the risk of going back under anesthesia is roughly equivalent between the two procedures. It is important for families to appreciate that the return to the operating room (OR) with regrowth after ITA is elective and controlled, whereas with post-ETA tonsil hemorrhage it is both emergent and potentially life-threatening. Once parents comprehend this, it is rare that they choose ETA when ITA is indicated.

Those surgeons whose training and experience lead them to favor ETA often report that when they offer their patients ITA, families usually choose ETA. Most likely this reflects their own bias. In general these surgeons either trained before ITA was commonplace, or their residency program offered limited or no ITA training. For the last 18 years, having taught ITA to 3-4 residents/year – residents who were also exposed to attending physicians who favored ETA--they have all, as far as I am aware, embraced ITA.

I agree with Dr. April's approach, with the following additions.

PREOPERATIVE CONSIDERATIONS

The decision to order sleep studies should be guided by AAO-HNS guidelines, and does not have any bearing on whether to perform ITA or ETA. Sleep studies are most useful when one suspects severe obstruction, in that they can guide postoperative care plans (such as the need for hospitalization or intensive care) and serve as a measure for improvement if repeat studies are indicated postoperatively. Sleep studies are also useful for when the history and/or physical exam is underwhelming, yet family or another provider strongly advocates for surgery.

Isolated tonsil asymmetry is not a risk factor for malignancy. Rather, it is a manifestation of asymmetrically positioned tonsils of equivalent volume. In asymmetric tonsils, ITA works well when indicated.

Tonsil hypertrophy after organ transplantation may suggest posttransplantation lymphoproliferative disorder. In our tertiary practice this is the most common tonsil neoplasm, and when this or any other malignancy is suspected, ETA should be performed. ITA works well for hypertrophic tonsils with tonsilliths, as long as the surgeon is careful to obliterate all crypts.

Sickle cell anemia tends to lead to auto-infarction of the spleen, which often leads to compensatory hypertrophy of the tissue in Waldeyer's ring. Rates of recurrent tonsil hypertrophy are very high in these patients, so in this setting, I prefer ETA.

Children may present with both allergic rhinitis and tonsillectomy and adenoidectomy (T&A) hypertrophy. If their symptoms cannot be controlled with allergy treatment, parents should be alerted that T&A surgery will not alleviate allergies. Most children I see with suspected recurrent tonsil and/or adenoid tissue growth have allergic rhinitis without recurrent T&A growth.

Teenage females with obstructive sleep apnea (OSA) plus any symptoms suggesting hypothyroidism (such as sluggishness, cold intolerance, or hair loss) should have a screening thyroid-stimulating hormone (TSH) level obtained before considering surgery for tonsil

obstruction. This pertains to either ITA or ETA. Very rarely clinically significant hypothyroidism will be diagnosed. Also regardless of whether planning to perform ETA or ITA, children with suspected or confirmed severe OSA should have preoperative cardiac echocardiography to rule out right heart dilation.

Retrospective study has confirmed our suspicion that ETA is not more beneficial than ITA for reducing OSA [1]. Dr. April has astutely observed that the lateral pharyngeal scarring often seen after ETA (and never seen after ITA) may worsen sleep by pulling the palate inferiorly and thereby narrowing the pharyngeal aperture. Because of the multiple variables influencing sleep apnea, it would be very difficult to confirm this hypothesis through randomized controlled trials (RCTs). Nevertheless, there is no basis for the argument that ITA is “partial” and therefore less effective than “total” ETA. If anything, the inverse may be true because ITA results in less palatal tethering.

Children who demonstrate abnormal speech patterns suggesting hypernasality (as opposed to the typical hyponasality caused by T&A hypertrophy) may need a preoperative speech evaluation. If they are found to have hypernasal speech or if they have a bifid uvula (with or without hypernasality), a T&A is not contraindicated. However, there is greater reason to perform ITA relative to ETA; not only does the powered instrument allow precise superior adenoidectomy, but the lack of postoperative scarring in the tonsil fossae will allow the child the best chance for normal speech and for the lack of palatal tethering mentioned above.

Some patients have difficult-to-treat conditions leaving them more at risk for persistent sleep apnea after tonsil surgery. These include patients with morbid obesity, macroglossia, micrognathia, other craniofacial malformations, laryngotracheal obstruction, and/or unfavorable Mallampati classifications. Given the uncertain impact of residual (1+ or smaller) tonsil tissue on OSA, and the possibility that ETA might be eventually recommended for a patient with residual OSA after ITA, I will often perform an ETA on these children simply to spare them the burden of having to consider an ETA, perhaps for the wrong reasons, at a later date.

Other children are particularly vulnerable to postoperative pain and dehydration; therefore, there is greater reason to consider ITA. These include children with asthma, failure-to-thrive, developmental delays, autistic spectrum disorders, other communication disorders, and syndromic conditions, including Down’s syndrome. Note that Down’s syndrome patients are vulnerable to both postoperative OSA, as well as postoperative pain and dehydration. This necessitates a more detailed conversation with the family. In most cases, ITA is the better operation for these children.

Teenagers tend to have more chronic tonsil inflammation than younger children, which usually results in more intraoperative bleeding, for both ETA and ITA. Because teenagers can usually be reasoned with to drink even when they have pain, and because their larger blood volume makes them less likely to exsanguinate from hemorrhage, ETA is less dangerous for them. ITA is often still the better choice.

Retrospective study suggests that ITA works as well as ETA for recurrent tonsillitis [2]. This has not been studied prospectively. Intuitively, IT should reduce infection by making the tonsil more resistant to biofilm adhesion and readily penetrated by the host’s circulating immune factors. Anecdotally, I have found IT to be extremely effective for reducing recurrent tonsillitis and pharyngitis in hypertrophic tonsils, certainly as effective as ETA. However, patients should not have ITA if they have a recurring tonsillitis indication but small,

contracted and/or endophytic tonsils. In my experience these patients often continue to have recurring infection even after ETA. Bluestone's classic study did not measure tonsil size. This is an area that warrants further study in a prospective manner.

INTRACAPSULAR TONSILLECTOMY TECHNIQUE

Unlike Dr. April, I do not find it necessary to cover the blade on entering the oral cavity, although I agree with him regarding the great care required by the surgeon. The instruments settings allow for the blade to rotate into a closed setting if desired. I prefer to leave the blade open to use as suction if needed. When using the blade to suction, it is important to only touch tissue with the blunt tip rather than the open suction port. Do NOT engage the uvula or non lymphoid into the blade's open suction or the tissue will become traumatized, leading to unnecessary postoperative pain. The surgeon should keep his/her foot OFF of the foot pedal until ready to shave tissue, so as to avoid inadvertently shaving lips, tongue, or uvula.

Like Dr. April, I started performing ITA with 1500 RPMs. I now use 3000 RPMs. Supposedly a slower speed allows more tissue to be suctioned into the blade and is therefore more aggressive. The difference is subtle, and I do not think it matters much. Occasionally, a neophyte circulator will set the machine to 5000 RPMs, at which a less effective resection is more evident.

I wholeheartedly agree with Dr. April's pointers on using the Hurd elevator to deliver tonsil tissue while protecting the posterior pillar and tongue base. However, not all patients have a recess between the tonsil and these structures. These anatomic variations are made important by this operation, but have not been described. When tonsil tissue extends to the medial edge of the posterior pillar or onto the tongue base, it is far preferable to leave residual tissue that can then be cauterized than to shave into the tongue or pillar.

Shaving both tonsils before cauterizing saves time. Only rarely is there enough bleeding for this to seem unwise. When I first did this procedure I cauterized prudently so as to minimize pain, using the well-established principle of ETA surgery. However, with time it became evident that the extent of cauterizing intact lymphoid tissue did not correlate with pain. The exception to this principle is that any cautery of adjacent tissue or through a defect in the tonsil capsule markedly increases pain. As a routine, I aggressively cauterize all residual tonsil tissue, as it results in some thermo-desiccation of tissue that cannot be safely shaved.

I try to maximize tonsil removal without penetrating the tonsil capsule. When it is unclear if more tissue should be shaved, I will err on the side of leaving excess tissue to minimize the risk of capsule penetration. I do not distinguish between routine and extended IT. I find that otalgia and significant pain are uncommon and do not correlate with the amount of lymphoid resection or cautery used.

I do not distinguish between inferior or superior tonsil tissue when applying cautery and I generally do not find it necessary to take time to let down the red rubber catheters. Dr. April's observation that this move improves visibility is worth remembering when better exposure is needed.

The left side is easier for a right-handed surgeon, and vice versa, so starting there facilitates a smooth pace of surgery. I always use my contralateral hand for the blade and my

ipsilateral hand for the Hurd. Dr. April's point that this is a more aggressive posture is well-taken. I do not have a script for where I start, rather I remove whatever seems easiest. The more tissue that is removed, the more difficult the procedure becomes. The most difficult aspect of the procedure is knowing when to stop. As one approaches the capsule, the tonsil changes color from a greyish pink hue to a redder appearance. The tissue begins to bleed more easily. The existence of crypts indicate that more tissue can be resected. One can gently probe the crypts with the Hurd or blade tip to assess the crypt depth, and then resect more tissue until the crypt is obliterated.

It is best to hold the handpiece near where it connects to the blade, rather than on the side further from the patient where the suction attaches. By holding the instrument closer to the patient, it is possible for the surgeon to gently rest 1-2 fingers on the patient's face or the Crowe-Davis retractor, which gives better balance.

Most tonsils have a shape somewhat akin to an upside-down teardrop: they are thin inferiorly like the pointed top of a teardrop, and thick superiorly, like the broad base of a teardrop. Consequently, one should be prepared to very cautiously resect tissue inferiorly, as there is usually not much there. As Dr. April mentioned, recurrent tonsil growth most commonly happens superiorly; by lateralizing the superior aspect of the anterior pillar with the Hurd, the surgeon can seek and resect most of the superior tonsil. Some tonsil tissue will often "hide" on the posterior-medial surface of the superior anterior pillar. To effectively expose this tissue, only 1-2 mm of the Hurd should be engaged to lateralize the anterior pillar; if too much of the Hurd engages the anterior pillar, it will cover rather than expose the remaining tonsil.

There is no need to routinely suction the stomach post-operatively. It adds an unnecessary minute to the procedure and does not reduce nausea. Exceptions would be if the patient has severe GERD, was known to have swallowed blood intraoperatively, or was thought to have possibly violated the nil per os (NPO) instructions.

Similarly, there is no need to completely close the Crowe-Davis and then re-open it a moment later to check for bleeding. That makes sense in ETA if the surgeon is worried about an artery on stretch, but it does not apply to ITA. I have not considered Dr. April's technique of closing the retractor 1 notch for irrigation, but that makes good sense, in that tongue discomfort is probably the biggest source of postoperative irritation.

In keeping with AAO-HNS guidelines, we always give intraoperative steroids; antibiotics are not given as routine but occasionally a child will have severe sinusitis for which we opt to begin antibiotics with an IV dose.

POSTOPERATIVE CARE

Caregivers are educated that a fever beginning 24-48 hours after surgery, and halitosis shortly thereafter, are normal. No dietary restrictions are given. Instead, the importance of hydration is emphasized, especially via water intake. Parents are told to practice common sense and offer "what you would want if you had a sore throat." Many children return to a nearly normal diet within 24 hours.

Children are given permission to return to all normal activities, including school and sports as soon as they have no pain or fever. This can take anywhere from 1-7 days. In

general, younger children tend to struggle more the first 24 hours, but recover faster than teens. Children under 3 years old, without additional comorbidities, can be safely managed as outpatients after ITA [3]; if problems arise during induction, extubation or in recovery, overnight admission merits greater consideration

Only three of my more than 2,000 patients have had postoperative bleeding. Two responded to cold-water gargles. The third, a college student, required silver nitrate. Both the pain and the risk of bleeding after IT parallel that experienced after adenoidectomy, because in both cases a thin layer of residual lymphoid tissue protects underlying soft tissue, nerves, and blood vessels. The difference in postoperative bleeding between ITA and ETA patients (who continue to suffer postoperative bleeding in 1-5% of case) is staggering. Although our literature recognizes the difference, in my opinion, the magnitude of the difference has been under-represented in published material. Children die after ETA every year, usually from exsanguination or narcotic overdose. I am not aware of any child ever dying after ITA. The significance of this point cannot be overemphasized.

All patients have 24/7 access for concerns and receive a call from a physician extender 5-10 days postoperatively. Routine follow-up is unnecessary, unless a child experiences unexpected problems. Children with documented severe OSA preoperatively or ongoing sleep disordered breathing should be considered for postoperative sleep study.

ACKNOWLEDGMENT

I would like to thank Dr. April for taking the initiative to serve as editor of this important publication and for inviting me to contribute my perspective.

Chapter 168

EXTRACAPSULAR TONSILLECTOMY IN 2017

Lyuba Gitman and Nira A. Goldstein

Division of Pediatric Otolaryngology, State University of New York Downstate
Medical Center, Brooklyn, NY, US

ABSTRACT

There are multiple techniques that have been described for extracapsular tonsillectomy. This chapter will review the current literature and provide multiple videos of the techniques.

Keywords: tonsillectomy, extracapsular tonsillectomy, PEAK plasmablade, complete tonsillectomy, monopolar cautery tonsillectomy

INTRODUCTION

Although tonsillectomy historically ranks as one of the most common surgical procedures performed, numbers declined with the advent of antibiotics in the middle of the 20th century, with a steady decline since the 1970s. Currently, the operation is performed at what appears to be about half the rate of 40 to 50 years ago [1]. Nevertheless, tonsillectomy or adenotonsillectomy (T&A) remains one of the leading pediatric surgical procedures in the United States [2]. Thirty years ago, approximately 90% of tonsillectomies in children were performed for infections (otitis media, chronic, or recurrent tonsillitis). Currently, upper airway obstruction (obstructive sleep apnea) is the main current indication with close to 80% of tonsillectomies done for this reason versus 20% for infection [3]. However, the complications associated with the procedure have not changed much over time. Tonsillectomy versus T&A are often grouped together, but tonsillectomy and adenoidectomy are separate operations with distinct indications.

This chapter describes extracapsular tonsillectomy in the current times (2017), including newer techniques using new technology, such as bipolar electrocautery, radiofrequency ablation, PEAK plasma blade, and laser tonsillectomy, as well as a brief comparison of

extracapsular versus intracapsular tonsillectomy (discussed in further detail in Chapter 170), and the complications associated with these procedures.

HISTORY OF TONSILLECTOMY

Removal of the tonsils has been practiced since antiquity, with Cornelius Celsus describing blunt removal of inflamed tonsils by using a finger in the first century A.D. in Rome. Later, in the 1600s, other practitioners used a modified guillotine-type instrument that had initially been used for uvulotomy to perform tonsillotomy. Snares were also used for tonsillotomy during this period [1].

Early tonsillectomies were hindered by the lack of anesthesia; therefore, surgeons tried to operate as quickly as possible. To speed up the procedure, Shulder's guillotine was introduced, and to simplify this, a reverse guillotine was used for enucleation [1].

In 1917, Samuel J. Crowe reviewed a series of 1000 tonsillectomies performed at Johns Hopkins Hospital between 1911 and 1917. Crowe also described his operative technique. The patient was placed in the recumbent position, with the foot of the table elevated slightly. Ether vapor was used for anesthesia. A special mouth gag, subsequently called the Crowe-Davis mouth gag, was used to open the mouth, retract the tongue, and direct the anesthetic agent to the hypopharynx. The tonsils were removed by sharp dissection. All bleeding points were clamped and ligated with black silk. Crowe's work laid the foundation for cold-knife dissection tonsillectomy. Prior to sutures becoming popular for hemostasis, other early agents for controlling bleeding included pressure and caustic agents; later on catgut, and silk noose ties were used [1]. The delivery of an inhalational anesthetic via a tube placed endotracheally became a more routine practice in the 1950s as a result of the recognized advantages of providing protection against aspiration and pulmonary abscesses, which were frequent and serious complications of tonsil surgery [4]. However, initially, these inhalation agents were extremely flammable, which limited the use of electrosurgical devices. Thus, electrical instruments in tonsil surgery, although previously attempted, did not gain popularity at this time because of both the anesthetic hazards and the lack of knowledge of electric currents and inexperience of surgeons with electrical instrumentation. The use of a monopolar electrosurgical unit in tonsil surgery started to become more common in the 1960s; however, at that point it served only to achieve hemostasis at the end of the procedure. It was not until the early 1980s that a suction coagulator and the "electrocautery" blade were introduced as primary instruments to actually remove tonsil tissue, a so-called "hot tonsillectomy" [4]. The more recent advents of newer technology all aim to decrease intra-operative blood loss and operative time, as well as minimize post-operative pain and morbidity as much as possible.

INDICATIONS

Prior to discussion of the tonsillectomy technique, or any surgery technique, it is vital to know the indications for the procedure. Tonsillectomy is a major surgery with potential morbidity and even mortality. Careful preoperative management and evaluation are necessary. The two major categories of indications are infectious and obstructive.

Table 1. [6] Paradise criteria for tonsillectomy

Criterion	Definition
Minimum frequency of sore throat episodes	7 or more episodes in the preceding year, OR 5 or more episodes in each of the preceding 2 y, OR 3 or more episodes in each of the preceding 3 y
Clinical features (sore throat plus the presence of one or more qualifies as an episode)	Temperature > 38.3°C OR Cervical lymphadenopathy (tender lymph nodes or >2 cm), OR Tonsillary exudates, OR Positive culture for group A beta-hemolytic streptococcus
Treatment	Antibiotics had been administered in conventional dosage for proved or suspected streptococcus episodes
Documentation	Each episode and its qualifying features had been substantiated by contemporaneous notation in a clinical record, OR <i>If not fully documented</i> , subsequent observance by the clinician of 2 episodes of throat infection with patterns of frequency and clinical features consistent with the initial history

With infections, recurrent and/or chronic tonsillitis, as well as greater than one previous peritonsillar abscess are the usual accepted indications for tonsillectomy. A Cochrane review of the effectiveness of adenotonsillectomy by Burton and Glasziou in 2009 concluded that the benefits of surgery were the greatest for those patients fulfilling the “Paradise criteria,” [5] with documented cultures and antibiotic use for the infections (Table 1) [6].

Upper airway obstruction, including sleep disordered breathing (SDB) and obstructive sleep apnea syndrome (OSAS), has replaced recurrent pharyngitis as the most common indication for the removal of tonsils and/or adenoids in children [7]. The estimated prevalence of OSAS among children is approximately 1% to 5%, and untreated OSAS in children leads to cardiovascular and metabolic comorbidities, cognitive and learning deficits, and behavioral problems [8]. Although there are functional, neuromuscular, and other anatomical factors that contribute to pediatric OSAS, adenotonsillar hypertrophy is considered the most common cause of childhood OSAS, and adenotonsillectomy is the first line of treatment [8]. Although polysomnography is the gold standard for diagnosing OSAS/SDB in children, it is unnecessary to perform in every case and does not establish the effects of the sleep disorder on the child’s well-being. The initial approach to a child with suspected SDB should include a detailed history, including possible described (or recorded) pauses in breathing, as well as an assessment of comorbid conditions such as behavioral problems, poor school performance, decreased quality of life, failure to thrive, and enuresis, followed by physical examination [6].

Other reasons for extracapsular tonsillectomy include asymmetric enlargement with suspicion of neoplasm, recurrent hemorrhagic tonsillitis, and recurrent tonsillitis not fulfilling the “Paradise criteria.” Modifying factors for extracapsular tonsillectomy include: a child with multiple antibiotic allergies; specific clinical syndromes such as periodic fever, aphthous stomatitis, pharyngitis and adenitis (PFAPA); and rarely, dysphagia not responsive to more conservative treatment modalities. At times, urgent tonsillectomy is indicated, such as severe obstructive sleep apnea with associated hypoxemia unresponsive to oxygen or sepsis secondary to tonsillitis (when all other sources have been ruled out) that is not responding to broad-spectrum systemic antibiotics.

Intracapsular tonsillectomy has been accepted by many otolaryngologists as a technique that achieves the dual goal of surgical efficacy and reduced morbidity in the treatment of pediatric sleep apnea secondary to adenotonsillar hypertrophy. The technique, which involves leaving a thin rim of lymphoid tissue in the tonsillar fossae, and supporting data are reviewed in other chapters. In brief, interest in this technique has grown as a number of studies report advantages such as less pain and earlier return to diet and activity while still maintaining similar complications rates and low rate of tonsillar regrowth [9]. Proponents of intracapsular tonsillectomy cite equivalent outcomes for obstructive symptoms, with the possible benefit of reduced pain and morbidity because there is no breach of the tonsillar capsule or underlying pharyngeal musculature [10]. The potential downsides, however, to intracapsular tonsillectomy are infection in the tonsillar remnant, thus making infectious indications a potential contraindication to intracapsular tonsillectomy, as well as regrowth of tonsillar tissue. Although there is a paucity of studies in the literature with long term follow-up of tonsillar regrowth after intracapsular tonsillectomy, in a recent systematic review (2012) of randomized controlled trials comparing intracapsular with total tonsillectomy in the pediatric population done by Walton et al., there was no significant difference in regrowth of tonsillar tissue between the groups [10]. Some studies also demonstrate a higher likelihood of OSAS refractory to treatment with intracapsular tonsillectomy compared to extracapsular (total) tonsillectomy when comorbid diagnoses such as asthma and/or obesity exist [8]. In their systematic review, Walton et al. demonstrated that recovery-related outcomes, including secondary hemorrhage rate and number of days until pain free, for intracapsular tonsillectomy were superior to total tonsillectomy specifically in the pediatric population with obstructive symptoms [10].

PRE-OPERATIVE EVALUATION

Once the proper indications are met for tonsillectomy (+/- adenoidectomy), several steps should be taken prior to surgery. For any child with potentially loose teeth, dental consultation may be obtained. As stated above, sleep studies are not usually necessary for children with upper airway obstruction unless the diagnosis or the need for surgery is in question [6]. Children with a personal or family history of easy bruising or extensive bleeding should have coagulation tests performed pre-operatively. Those with von Willibrand or sickle cell disease require preoperative hematological optimization. Children with sickle cell disease require intravenous hydration while children with certain types of von Willibrand disease require preoperative desmopressin acetate (DDAVP). Those with coexisting medical conditions, such as asthma, cardiac disease, and seizures, should be assessed and optimized prior to surgery. There is no consensus regarding obtaining lateral neck films for children with Down syndrome to evaluate the cervical spine, however, caution should always be used in positioning this patient population given the high incidence of atlantoaxial instability [2]. A post-operative intensive care unit or observation bed is reserved for children less than 3 years old, as well as those with severe OSAS, significant medical problems, obesity, recent respiratory infection, neurologic delay, or craniofacial abnormalities [2, 6].

ANESTHESIA CONSIDERATIONS

General anesthesia is administered via a curved RAE endotracheal tube, which is placed in the midline of the lower lip and taped securely. Perioperative narcotics are avoided in patients with OSAS. Intra-operative corticosteroids may decrease postoperative pain and emesis and improve recovery following tonsillectomy. Most published studies recommend a dose of 0.5 mg/kg IV at the start of surgery (with maximum dose of 16 mg) [2, 6]. Multiple studies also demonstrate that ketorolac tromethamine (a parenteral nonsteroidal anti-inflammatory drug) should be avoided in the perioperative period (intra-operatively and within 24 hours after surgery) because it may increase bleeding.

PROCEDURE

Tonsillectomy can be performed via “cold” dissection technique or “hot” electrocautery technique. Many studies have debated the merits of each technique. With hot tonsillectomy techniques, thermal energy is used to cut and coagulate tissue in an effort to reduce operative time and intraoperative bleeding [2]. Evidence suggests, however, that none of the hot tonsillectomy techniques offer concurrent reductions in intra- and post-operative bleeding and pain compared with traditional cold-steel dissection with packs or ties [11]. Nevertheless, diathermy remains the most commonly used hot tonsillectomy technique. Although electrocautery for extracapsular tonsillectomy has been shown to increase post-operative pain in many studies, if dissection is performed carefully, this can be minimized. Later in this chapter, various new developments/instruments for “hot” tonsillectomy technique are reviewed.

The following is a Step-by-Step Outline of a “Hot” Extracapsular Tonsillectomy [2]

- A headlight is mandatory for adequate visualization.
- The table is positioned so that the surgeon has nonobstructed access to the patient’s head, while the anesthesiologist has access to the intravenous line and endotracheal tube.
- A shoulder roll is placed between the scapulae, the head is placed on a head “doughnut,” and a head drape is placed to cover the eyes. Caution needs to be exercised when using towel clamps as the face and/or eyes are at risk of being clamped under the head drape. Alternatively, a piece of tape can be used to hold the head drape.
- The patient is placed in Rose’s position by lowering the head, unless there is concern for atlanto-axial or other conditions affecting the cervical spine.
- An appropriately sized Crowe-Davis, McGiver, or Dingman mouth gag is carefully inserted, avoiding dental injury, and then suspended on a Mayo stand brought into the field. A wet tonsil sponge may be placed in the hypopharynx at this point to prevent leakage of anesthetic gases that can cause an intraoperative fire.

- Red rubber catheters are lubricated with soapy water, then inserted into the nasal cavity following the floor of the nose bilaterally in order to retract the soft palate. The catheters are brought out of the oral cavity and clamped to elevate the palate.
- The superior pole of one tonsil is pulled medially with an Allis clamp, which grasps the tonsil with the tines in a superior to inferior orientation. The mucosa overlying the superior pole is then incised with a protected straight electrosurgery tip (10 to 20 watts) at the junction between the tonsil and mucosal fold.
- Once the incision is made, the cautery tip can be used to identify the avascular plane between the tonsillar capsule and tonsillar fossa. Correct identification of this plane is essential.
- If the plane is not easily identified, a Metzenbaum scissors or tonsil clamp can be placed through the incision to help identify the plane.
- After the plane is identified, the Allis clamp can then regrasp the tonsil capsule and mucosal fold at the superior pole of the tonsil and be used to provide tension for the rest of the procedure.
- Dissection between the tonsillar capsule and fossa proceeds from superior to inferior, while an assistant suctions the plume.
 1. Medial traction is applied to the tonsil with the Allis clamp so that the cautery can gently lyse the intervening fibers without deeply penetrating the muscular fossa.
 2. Traction on the tonsil is continually re-assessed to provide maximum tension and visualization of the fibers, as well as the blood vessels between the tonsil capsule and fossa.
 3. Dissection is performed with only the tip of the cautery, staying right on the tonsillar capsule to limit the delivery of current to surrounding tissues. This is because muscular penetration by the cautery tip can result in increased postoperative pain and possibly a greater risk of postoperative bleeding.
- The cautery continues around the inferior pole of the tonsil until the tonsil can be completely removed. The plane between the inferior palatine and lingual tonsil must be established to prevent over-aggressive removal of lingual tonsil, which is accomplished by sweeping the cautery from lateral to medial when cauterizing at the inferior pole.
- After the tonsil is removed, hemostasis is established with a suction cautery (15 to 30 watts), and a Hurd dissector to retract the anterior and posterior tonsillar pillars for visualization. The cautery should not burn deeply; rather the bleeding tissue should be pulled into the suction lumen and then cauterized. Also note: the superior pole of the tonsil can be visualized with a laryngeal mirror for better hemostasis in this region.
- Visible vessels or persistent bleeding may require a figure of eight stitch using a plain or chromic gut suture on a semicircular needle. Hemostatic sutures must be placed superficially to prevent deeper vascular injury.
- Other hemostatic techniques include prolonged packing, ties, bismuth, bipolar cautery, Avitene™ microfibrillar collagen, and topical thrombin.
- Before removing the contralateral tonsil, the mouth gag should be taken down for one minute between sides to minimize the chances of tongue edema.

- Once both tonsils are safely removed, the nasopharynx and oropharynx are irrigated to assure hemostasis and to identify residual adenoid or tonsil tissue that could be aspirated. The red rubber catheters are removed. An appropriately sized nasogastric tube is used to empty the stomach.
- The mouth gag can be taken down for one minute to allow the tissue to relax, and then re-opened to ensure hemostasis. Once complete, the mouth gag should be removed with the thumb pressing down on the lower lip area to prevent premature extubation.
- The child is then extubated by the anesthesiologist, though the surgical team should supervise the process and ensure that there is no excessive bleeding or other difficulties, such as laryngospasm [2].

POST-OPERATIVE CARE

As discussed above, observation overnight in the inpatient ward or intensive care unit is recommended post-tonsillectomy for children less than 3 years old, children with severe OSAS, children with significant associated medical problems, neurological delay, or craniofacial abnormalities, or those with recent respiratory infections. The remaining patients may be safely discharged after 3 to 4 hours of observation after surgery in the post-operative anesthesia care unit, provided that there are no significant desaturations, no bleeding, and the child is tolerating an oral diet [2].

Clinicians should not routinely administer or prescribe perioperative antibiotics to children undergoing tonsillectomy [6].

There is no consensus on activity resumption after tonsillectomy with or without adenoidectomy, with every child responding differently to surgery. Some general principles include avoiding strenuous activity for 1 to 2 weeks after surgery and returning to school or daycare 5 to 7 days after surgery. There are many approaches to postoperative diet, ranging from soft diet for 1 to 2 weeks to resumption of normal diet on the same day as surgery. Hard foods, or foods that may cause discomfort, should be avoided initially (up to 1 week) [2].

The surgeon should advocate for pain management after tonsillectomy and educate caregivers about the importance of managing and reassessing pain [6]. Narcotics are avoided in children with OSAS to prevent respiratory depression.

POST-OPERATIVE MORBIDITY/COMPLICATIONS

The complication rate for tonsillectomy has declined over the years, although the types of complications remain the same: bleeding, alterations in voice, aspiration, oropharyngeal stenosis, pneumonia, and rarely, death [1]. The potential for significant morbidity, even death, is inherent in the procedure. Traditional, “cold-knife” surgical techniques utilizing the scalpel, guillotine, or snare have largely been replaced with techniques utilizing cautery, or “hot” technique, to limit intraoperative bleeding [9]. However, use of electrocautery is fraught with its own complications of prolonged pain, poor oral intake, risk of dehydration, and increased risk of post-operative, secondary bleeding.

Post-tonsillectomy bleeding is the main and most dangerous complication connected with this procedure. It creates anxiety, prolongs morbidity, and increases healthcare costs [12]. Primary bleeding is defined as postoperative bleeding within 24 hours of the initial surgery. Secondary or delayed bleeding, which is more common in this day and age, is defined as bleeding that occurs >24 hours after the procedure. Although variable rates have been described in the literature, from 0.2% to 3% for primary hemorrhages and 1 to 7% for secondary hemorrhages [13], the general consensus is that on average there is about a 1 to 2% risk of post-tonsillectomy hemorrhage [2]. Multiple studies also demonstrate a lower hemorrhage rate in patients undergoing tonsillectomy for pharyngeal obstruction only, as compared to those with infectious indications [14].

Another major complication/morbidity is post-operative pain, which is associated with poor oral intake, and possibly dehydration requiring monitoring in the emergency room or at times, re-admission. Because of swelling from surgery, there is a chance of airway obstruction in which the child is continuously desaturating post-operatively, which at times may require observation in an intensive care unit, parenteral steroids, racemic epinephrine, and consideration of re-intubation, if necessary. Post-obstructive pulmonary edema may be another reason for desaturations post-operatively, which results from increased intrathoracic venous and hydrostatic pressure relieved by intubation or surgery. Pink frothy secretions usually accompany desaturations, and diuretics and/or re-intubation with positive pressure ventilation may be necessary [2].

Atlantoaxial subluxation (Grisel's syndrome) is rare with tonsillectomy alone. Children present with persistent torticollis 1 to 2 weeks after surgery. Neurological or orthopedic consultation may be required. Mandible dislocation, although rare, is also a possibility secondary to patient movement while in suspension with the mouth gag in place [7].

Iatrogenic complications after tonsillectomy include dental injury from intubation or mouth gag insertion, requiring urgent laryngoscopy and bronchoscopy for any newly discovered missing teeth. Oropharyngeal stenosis may occur, caused by excessive removal of the deep lower tonsil pole and adjacent lingual tonsil tissue. Internal carotid artery injury after deep cautery, suturing, or dissection may occur, as the artery lies within 5 to 30 mm of the lateral tonsil fossa [2]. Lingual nerve palsy, caused by pressure from the tongue blade of the mouth gag may also occur, however, this complication is generally temporary. Cautery burns, either perioral or intra-oral, caused by operator error or equipment malfunction may also pose serious problems, on rare occasions requiring further surgery for reconstruction. Since the advent of general endotracheal intubation with protection of the airway, aspiration and pneumonia occur more rarely than they once did; however, there is always a possibility of aspiration of refluxed gastric contents during induction if the child was not nil per os (NPO), as well as a risk of aspiration of blood/tissue during the procedure.

Lastly, persistent OSAS, especially in obese children or children with other craniofacial deformities, is a well-described risk that all parents/caretakers must be counseled on thoroughly, as is the possibility of tonsillar regrowth. There is a theoretical increased chance of regrowth when intracapsular tonsillectomy is performed; however, there is a paucity of evidence-based articles in the current literature with long-term follow-up for tonsillar regrowth after partial tonsillectomies [9].

HOT VS. COLD TONSILLECTOMY

Although tonsillectomies remain one of the most commonly performed pediatric surgeries in the United States, there is an absence of universal agreement on the surgical method and extent of removal [9]. Ideally, tonsillectomy should be fast, bloodless, and associated with rapid and uncomplicated recovery [12]. Diathermy involves the use of high-frequency electrical current to cut tissue, remove the tonsil, and control blood loss. Electrosurgical instruments all achieve cutting and simultaneous hemostasis by sealing the blood vessel lumen by virtue of tissue heating [13]. Cold knife dissection traditionally refers to the method where the tonsil is cut away and blood loss is then controlled with ties, stitches, or diathermy [15]. Although “hot” techniques using electrodissection have become more popular as they provide advantages of diathermy for hemostasis intraoperatively as compared to cold-knife dissection, there is a question of whether this statistically significant difference is clinically significant, especially in children over a certain weight [16]. To further complicate the question, there are multiple studies that demonstrate not only increased pain, but also the same or even increased rate of secondary post-tonsillectomy hemorrhage when compared to “cold-knife” techniques. In a prospective, randomized, single-blind, controlled clinical trial published in 2000, Nunez et al. demonstrated that the hot dissection tonsillectomy group took 7.5 more doses of analgesics than the cold dissection group. The hot dissection group also took 2.5 more days than the cold dissection group to regain a normal diet. Nunez concluded that hot dissection tonsillectomy increases morbidity in pediatric patients in the recovery period following hospital discharge [16]. In another prospective study of 440 patients who underwent electrodissection tonsillectomy published in 2001, Blomgren et al. concluded that monopolar electrodissection tonsillectomy was fast and resulted in little intraoperative bleeding. However, postoperative hemorrhages were shown to be common in this group, and the mean use of analgesics was greater than 10 days [12], thus concluding that even though monopolar electrodissection technique for tonsillectomy has its advantages, it is far from optimal and better methods still needed to be developed [12].

In their systematic review of hot versus cold tonsillectomy published in 2003, Robert et al. compared monopolar electrocautery versus cold knife dissection tonsillectomy. Pooled data from 6 articles meeting their selection criteria confirmed much of the above, demonstrating that electrodissection increases pain in comparison to sharp dissection, and that postoperative hemorrhage rates are not significantly different when comparing the two methods [17]. However, as previous studies demonstrated, they also verify that intraoperative blood loss and operative time are less with monopolar electrocautery techniques [17].

A recent Cochrane review published in 2011 by Pinder et al., comparing the two methods, found two relevant studies that fulfilled their inclusion criteria. Their findings were similar to those discussed above and concluded that there was not enough evidence to demonstrate that diathermy was more effective than cold dissection. No differences were found in either the primary or secondary hemorrhage rates when comparing cold versus hot techniques. This finding may be due to the fact that the studies included in this Cochrane review were insufficiently powered to pick up small differences in such rates. They also comment that there was some evidence that patients who had diathermy tonsillectomy had less bleeding during the operation but more pain afterwards, however, more research was needed [15].

EXTRACAPSULAR VS. INTRACAPSULAR TECHNIQUES

As discussed earlier, the techniques of tonsillectomy can be broadly divided into 2 major categories: extracapsular (total tonsillectomy, subcapsular) and intracapsular (partial tonsillectomy, “subtotal” tonsillectomy, tonsillotomy). Extracapsular tonsillectomy involves dissecting as described above, lateral to the tonsil in the plane between the tonsillar capsule and the pharyngeal musculature, and the tonsil is generally removed as a single unit. Partial tonsillectomy, or intracapsular, involves removal of most of the tonsil while preserving a rim of lymphoid tissue and tonsillar capsule. As discussed above, the indications for which technique is used differ slightly: either extracapsular or intracapsular tonsillectomy can be performed for the pediatric patient with OSAS, however for patients undergoing the procedure for infectious causes (tonsillitis/peritonsillar abscess), the extracapsular technique is recommended. The most common extracapsular techniques use a “cold” knife (sharp dissection), monopolar electrocautery, bipolar electrocautery (or bipolar scissors), or harmonic scalpel. Intracapsular techniques may use the microdebrider, bipolar radiofrequency ablation (which can be used to remove the entire tonsil as well), and carbon dioxide laser [18].

The following is a review of the various techniques/technology that have been introduced to tonsillectomy since the 1980s.

BIPOLAR ELECTROCAUTERY/BIPOLAR SCISSORS

In bipolar diathermy, a current passes through the tissue between the tips of a pair of forceps. The electrical energy is concentrated in a small area, therefore, the tissue heats extremely rapidly, resulting in coagulation of blood vessels [15]. Bipolar administration of radiofrequency currents results in less electrical energy being leaked to distant tissues, and thus more precise coagulation [13]. In a randomized controlled study (1997), comparing bipolar diathermy using binocular microscope to cold knife dissection, Kujawski et al. demonstrated less intraoperative hemorrhage in the bipolar group, no episodes of primary hemorrhage in either group, and no difference in secondary hemorrhage between the groups, although there were few secondary hemorrhages in either group. There was also no difference in the mean operating time between the two groups, however, both times were significantly longer than the average for monopolar dissection (36.9 minutes for diathermy and 35.9 minutes for dissection) [15].

In 2000, Pizzuto et al. published a prospective randomized study comparing microbipolar dissection (bipolar dissection with microscope, MBPD) to hot knife and cold knife/cautery techniques using 400 consecutive patients presenting for tonsillectomy. They found that postoperative bleeding of any kind was significantly less in the microbipolar dissection group (compared to both hot and cold knife), the need for postoperative intervention for bleeding was also significantly less in the MBPD group, and the return to normal activity occurred 2 days earlier for the MBPD group. Intraoperative blood loss was similar in all treatment groups, however, operative time was 3 to 5 minutes longer for MBPD (24.2 min) than for cold knife with cautery (21.1 min) or hot knife (16.5 min) respectively [19].

In contrast, Schrotzlmaier et al., in their prospective study published in 2015, assessed postoperative pain in 48 patients who underwent bipolar tonsillectomy on one side using a microscope or magnifying glasses and on the other side using unsupported vision. In terms of their primary outcome, post-operative pain, they found that patients did not suffer less pain when magnification devices had been used. Secondly, the authors comment that there was no statistically significant difference in operative time when comparing the use of microscope versus magnifying glasses versus unaided vision. Due to the relatively low number of patients, and consequently low number of bleeding complications, a statistical comparison between the treatment groups with regard to postoperative hemorrhage could not be drawn [20].

One of the main issues with bipolar tonsillectomy is the greater surgical time, as compared to monopolar tonsillectomy, in part because of the frequent need to clean char from the bayonet forceps [13]. Bipolar electrosurgical scissors combine the blunt dissecting capacity and precise cutting of cold scissors with a technology that allows for coagulation of vessels before their division. In addition, because the layer of plastic fused to one blade of the scissors is harder than steel, it continuously cleans and sharpens the opposite blade, thus preventing the accumulation of char that slows the use of most bipolar instruments [13]. These instruments were introduced in the US market in the spring of 1997 [13]. Isaacson et al. first published a pilot study in 1998 on 30 consecutive pediatric tonsillectomies demonstrating their favorable experience using bipolar electrosurgical scissors. They describe their technique, which deviates slightly from the classic hot or cold knife method. The back surface of the 7-inch Metzenbaum scissors is insulated with a strip of polyvinyl chloride electrical tape. The tonsil is grasped near its superior pole with a curved tenaculum and drawn medially, while the uvula is distracted superiorly by an assistant using a Yankauer suction. With the tonsil on tension, the superior edge of the anterior pillar is incised with the scissors in electrified mode (bipolar power setting 20). The anterior pillar mucosa is then incised from superior to inferior with the scissor in nonelectrified mode. A pocket is created by blunt dissection between the lateral tonsillar surface and the superior constrictor muscle. Identified vessels are coagulated and then divided with the scissors in electrified mode. Dissection is carried to the inferior pole, dividing the posterior tonsillar pillar mucosa sharply. The scissors are again set in electrified mode to slowly divide the inferior pole vessels and lymphoid tissue to complete the dissection. Minor bleeding during dissection can be controlled by using the tips of the scissors as a bipolar forceps on either side of the bleeding point. A monopolar suction cautery supplements bipolar coagulation as needed [13]. In the pilot study, the average operative time for tonsillar removal was 6 minutes. There were no immediate or delayed post-tonsillectomy hemorrhages in a 2 week follow up of the thirty patients who underwent tonsillectomy with bipolar scissors. In an update, the authors comment that out of 209 consecutive tonsillectomies using this instrument, there were no immediate postoperative hemorrhages and only 4 delayed episodes [13].

Raut et al. studied bipolar scissors, comparing this instrument to cold dissection tonsillectomy in a prospective, randomized trial in 200 patients undergoing surgery for chronic tonsillitis. The morbidity rate, including pain scores and primary and secondary hemorrhage rates, was similar to that of cold dissection. The median amounts of intraoperative blood loss were significantly less than with cold dissection, however, the mean operating time was increased in the bipolar scissors group (20 minutes) when compared to cold dissection (13 minutes) [1]. There was no statistically significant difference in the pain

scores between the two methods. The primary and secondary hemorrhage rates were unaffected by the surgical method [21].

In a 2007 publication, the National Prospective Tonsillectomy Audit (NPTA), however, demonstrated an increase in postoperative hemorrhage using bipolar electrodissection or bipolar scissors as compared to the cold knife technique. The NPTA was established to investigate the occurrence of complications after tonsillectomy, especially postoperative hemorrhage, as well as risk factors for such complications. Data were collected electronically on more than 40,000 patients who underwent tonsillectomy in England and Northern Ireland between July 2003 and September 2004. For hemorrhage, compared with the cold steel group, bipolar diathermy tonsillectomy had an odds ratio of 2.47 (1.81-3.36) and bipolar diathermy scissors tonsillectomy an odds ratio of 3.20 (2.09-4.90). Use of bipolar diathermy for hemostasis only after cold steel dissection carried an intermediate risk, with an odds ratio of 1.67 (1.16-2.13) [14].

RADIOFREQUENCY ABLATION/COBLATION

Coblation tonsillectomy (see Chapter 169) is a variation of bipolar electrosurgery that generates lower temperatures (40 to 70 degrees Celsius) with the aim of minimizing thermal damage to surrounding tissues [11]. It can be used to perform an extracapsular or intracapsular tonsillectomy [18]. A series of electrodes on the tip of the coblation probe are bathed in a conducting saline solution that flows continuously through an irrigation sheath. Radiofrequency energy ionizes the saline to form a localized plasma layer of sodium ions. The heat generated by these ions cuts tissue and seals small blood vessels [11]. Coblation was initially introduced into the surgical world in the 1990s [22], and the coblation technique specifically for tonsillectomy began to be used in 2001 [23]. A systematic review of electrosurgery tonsillectomy in adults and children found that operative time was longest for coblation (24.5 minutes) and shortest for monopolar diathermy (15.5 minutes) [11]. The mean number of days to return to normal activity was similar for coblation, diathermy, and cold-steel dissection [22]. The data from the NPTA demonstrated an increased risk of postoperative hemorrhage using coblation compared to cold knife technique, with an adjusted odds ratio of 3.07 (2.03-4.65) [14]. This data demonstrated that for coblation both primary and secondary hemorrhage rates were high when compared to cold steel tonsillectomy [23].

In 2006, Mowatt et al. performed a meta-analysis of fifty primary studies (including randomized controlled trials, non-randomized comparative studies, prospective case series, and population based registry reports) in order to compare cold steel dissection with monopolar and bipolar diathermy, as well as with coblation technique. They found that coblation was associated with higher rates of secondary hemorrhage compared to cold steel dissection [22].

It appears that although it has been claimed that by operating at lower temperatures than diathermy, coblation may result in less tissue damage and improved healing, the literature demonstrates that it does not actually decrease the risk of post-operative bleeding, especially that of secondary hemorrhage.

ARGON PLASMA COAGULATION

Argon plasma coagulation (APC) is a monopolar form of coblation and may be used for extracapsular tonsillectomy. This non-contact technique uses a stream of ionized argon gas instead of saline as the medium for the electrical current. The current flows between the hand piece and the tissue and is dispersed to a neutral electrode attached to the patient [11]. The procedure is performed in a similar fashion to the general “hot” technique described above: the superior pole is grasped with forceps; the anterior pillar is then dissected with the APC dissector under activation of the plasma beam; the appropriate peritonsillar plane is identified and the tonsil is dissected from the tonsillar fossa under continuous APC activation until the lower pole of the tonsil is reached, with the tonsil removed in its entirety. With this method, similar to other “hot” techniques, dissection and coagulation are done in one step. In cases with increased vascularization, the speed of dissection may be decreased to allow sufficient coagulation [24].

Two randomized controlled trials (RCTs) assessed APC tonsillectomy. One RCT published in 2001 of 201 patients found no difference between argon plasma coagulation and cold steel dissection (with packs or ties) with respect to pain during the 10-day follow-up, but the operative time was significantly shorter with argon coagulation. This study also demonstrated that the rates of postoperative hemorrhage (total) were similar to those of cold steel dissection. The authors conclude that the APC technique does not face the general problem of electrosurgery or thermal coagulation techniques in which the postoperative pain is often increased compared with conventional cold techniques [24]. The other RCT (n = 40), published in 2003, found that operative time and pain less than 2 weeks after the procedure were similar for patients undergoing argon plasma coagulation, and for patients who had undergone cold-steel dissection or diathermy [25]. Both studies demonstrated that the mean intraoperative blood loss and mean duration of operative time were significantly lower compared with conventional tonsillectomy [11].

ULTRASONIC/HARMONIC SCALPEL

The ultrasonic scalpel (brand name: Harmonic scalpel, produced by Ethicon Endo-Surgery Inc, Cincinnati, Ohio) can be used to perform an extracapsular tonsillectomy. This instrument has a blade that vibrates at 55.5 kHz (55,500 cycles/second) over a distance of 80 micrometers to cut tissue. The heat generated in the tissue (between 50 and 100 degrees Celsius) by the blade’s movement coagulates the blood vessels [11] at a temperature lower than other hot methods such as diathermy or lasers, while simultaneously allowing for precise cutting. The blade oscillations dissect tissues by creating intra-cellular cavities as pressure waves are conducted through the tissues. The expansion and contraction of these cavities results in lysis of cellular connections, resulting in tissue dissection [18]. Although in theory no additional instrument is needed given its dual function, many studies describe the use of diathermy for full coagulation after the use of the ultrasonic scalpel [11].

One systemic review found five RCTs and four non-randomized comparative studies regarding the use of the ultrasonic scalpel in children and adults [26]. The pain scores less than 7 days after surgery were similar for the ultrasonic scalpel tonsillectomy, diathermy, and

cold-steel dissection. Two weeks after surgery, the pain was significantly worse after the ultrasonic-scalpel technique when compared to cold knife, however, the pain was better when compared to diathermy. There was a greater risk of secondary hemorrhage after ultrasonic scalpel tonsillectomy compared with cold-steel dissection. The follow-up period in more than half of the studies in this systemic review was too short or not stated, so the rates of secondary hemorrhage may also be underestimated [11].

In contrast to the above findings, in their meta-analysis comparing outcomes of tonsillectomies performed using the ultrasonic scalpel with tonsillectomies performed using cold knife combined with electrocautery for hemostasis, Alexiou et al. found no significant difference between compared groups regarding operative time, postoperative bleeding, and averaged postoperative pain. However perioperative bleeding was significantly less in the ultrasonic scalpel group [27]. In many of the existing studies, additional techniques were used to control bleeding (using diathermy after dissection with the ultrasonic scalpel, for example).

It is crucial to point out that the evidence base for this procedure is small, and generally of a low quality with significant heterogeneity in the results, as demonstrated above. The outcomes in the studies this systemic review describes were poorly assessed and reported, and most of the RCTs were small [26], thus putting into question both the internal and external validity of the available data on this technique.

LASER (CO₂, KTP)

The carbon dioxide laser, potassium titanyl phosphate (KTP) laser, and contact diode laser are the most commonly used lasers, and although traditionally they have been described for extracapsular tonsillectomies, they are increasingly being used for partial/intracapsular tonsillectomy as well. In this method, energy is delivered through a flexible optical fiber that is used as a scalpel to dissect tissue and separate the tonsil from the tonsillar bed while simultaneously coagulating vessels [28]. In the literature, however, other techniques are often used to control bleeding after laser dissection of the tonsil [11].

A systemic review published in 2006 found four RCTs, two non-randomized comparative studies, and one case series of laser tonsillectomy in adults and children. Most used the KTP laser. The pain within 24 hours was lower after laser tonsillectomy than after cold-steel dissection, but was subsequently greater less than 2 weeks postoperatively. Three studies found that wound healing was slower after laser tonsillectomy compared with cold-steel dissection. Whereas the mean intraoperative blood loss was lower with KTP-laser tonsillectomy compared to cold-steel dissection, there were slightly increased rates of postoperative hemorrhage. Despite using laser safety precautions, one patient in a case series sustained a burn to the tongue [11]. One prospective randomized study of 60 patients using the CO₂ laser with the power set to 10 to 15 watts demonstrated a significant decrease in operative time and amount of intraoperative blood loss as compared to conventional “cold” knife techniques, with no statistical difference in the two groups when looking at postoperative pain. Of note there were no postoperative hemorrhages reported in either group, with follow up between 2 weeks and 1 month post-operatively [28]. The authors here thus conclude that in a hospital where a laser machine and expertise are available, it is justifiable to use this technique as an effective method of performing tonsillectomy.

PEAK PLASMA BLADE

Recently the PEAK plasma blade has been used for extracapsular tonsillectomy (Video). The PEAK PlasmaBlade is a new electrosurgical device that uses pulsed radiofrequencies to generate a plasma-mediated discharge along the exposed rim of an insulated blade, creating an effective cutting edge while the blade stays near the patient's body temperature. One advantage of the hand piece for tonsillectomy is that it has a suction port, which obviates the need for an assistant to hold a Yankauer suction during the procedure. A recent study compared monopolar cautery extracapsular tonsillectomy, coblation extracapsular tonsillectomy, and PEAK PlasmaBlade extracapsular tonsillectomy. There was less bleeding and less frequent return to the emergency department for treatment [29] after the use of the PEAK PlasmaBlade.

POWERED INSTRUMENTS: MICRODEBRIDER

The microdebrider as an instrument was initially introduced by Koltai et al. in 1997 for adenoidectomy, and in 2002 for intracapsular tonsillectomy [7]. The microdebrider is a powered rotary shaving device with continuous suction, made up of a tube and connected to a hand piece, which in turn, is connected to a motor with foot control and a suction device [18]. Tissue reduction with the microdebrider is achieved by mechanically shaving the tonsillar tissue from the inferior medial pole proceeding superior laterally, preserving the tonsillar capsule along with a thin rim of tonsillar tissue. No significant heat is generated, thus avoiding any thermal damage to surrounding tissue [9].

Since the time of the microdebrider's introduction, multiple studies have demonstrated the safety and efficacy of microdebrider intracapsular tonsillectomy, making it a valuable treatment option for the appropriate candidates—importantly, children with tonsillar hypertrophy and obstructive sleep apnea [7]. The existing literature supports the evidence that intracapsular tonsillectomy (using any technique) has fewer incidences of delayed hemorrhage, less postoperative pain, and an earlier return to daily activities [9]. In their prospective, double-blinded study of 156 patients comparing intracapsular microdebridement, intracapsular coblation, and extracapsular electrocautery dissection published in 2009, Wilson et al. found that postoperative recovery following intracapsular adenotonsillectomy in children with OSAS is significantly earlier with the use of either the coblator or microdebrider versus traditional extracapsular tonsillectomy with electrocautery. The authors also demonstrated that the microdebrider and coblator for intracapsular tonsillectomy were equivalent in all parameters studied (intraoperative time, surgeon's perception of difficulty, postoperative pain, return to diet and activity, postoperative complications, cost) with the exception of shorter operative time and less cost for the microdebrider [9].

Major downsides of this technique include the possibility of recurrent tonsillitis, thus making an infection-related indication a relative contraindication to intracapsular tonsillectomy using any method, as well as tonsillar regrowth and the possible need for reoperation. In a retrospective cohort study published in 2016 looking at the charts of 89 children who underwent either intracapsular or extracapsular tonsillectomy for OSAS, Mukhatiyar et al. found that both are effective modalities to treat OSAS with comparable

surgical outcomes on short-term follow up, however, in the subset of patients with asthma and obesity, the OSAS was likely to be refractory to treatment with a partial technique, as compared to extracapsular tonsillectomy and adenoidectomy [8]. For this reason the decision of which technique to use, as in all surgery, involves looking at the patient as a whole. Lastly, microdebrider-assisted intracapsular tonsillectomy is criticized for increased intraoperative blood loss [7]. Although statistically significant in many studies, the difference in intraoperative blood loss with the microdebrider compared to electrocautery is (for the most part) not clinically significant [7]. It does, nevertheless, become significant in those children (or adults) with a low weight or for those with bleeding disorders or other risk factors for hemorrhage [23], which again emphasizes the importance of looking at all factors and weighing the risks and benefits of each technique based on the individual patient.

VESSEL SEALING SYSTEM

Energy-based vessel sealing systems use different technologies to provide a similar dissection-ligation effect. Thermal welding uses the simultaneous application of heat and pressure (instead of using electric current) to cut and coagulate tissue and blood vessels. Unlike diathermy, no electric current passes through the tissue. At the tip of the cautery forceps, a low voltage current activates a heating element. Tissue that is grasped using the forceps is vaporized (temperatures 300 to 400 degrees C), while the vessels are sealed by a combination of heat and the clamping pressure of the forceps [16]. The manufacturer claims that it produces less heat and minimizes collateral tissue damage [27].

No identified RCTs assessed thermal welding in children, but the technique was used in adults in several studies. In their randomized controlled study, Karatzias et al. found no difference in operative time between thermal welding and bipolar diathermy. Patients in the thermal welding group had less postoperative pain during the two week follow-up and returned to normal diet more quickly compared to bipolar diathermy [30]. There was no difference found between thermal welding and bipolar diathermy in both the mean intraoperative blood loss and in the rates of postoperative hemorrhage [30]. However, it is important to note that given this is a relatively newer technique, the existing evidence in today's literature consists of small patient numbers, therefore, further studies are necessary in order to support many of the above conclusions.

The LigaSure Vessel Sealing System (LS) is a hemostatic electrosurgical device that consists of a handpiece with a ratcheted scissors mechanism that grasps and compresses the tissue and an electrosurgical generator that senses the density of the tissue bundle, automatically adjusting the amount of energy to deliver the optimal amount to denature collagen and elastin within the vessel wall and connective tissue [27].

In a randomized clinical trial comparing LigaSure to cold-steel dissection, Lachanas et al. found that the mean operative time was significantly shorter and the pain was lower in the 2 weeks following the use of the vessel sealing system when compared to cold-steel dissection with packs or ties [31]. The mean intraoperative blood loss was lower using the LigaSure compared with cold-steel dissection, however, the rates of postoperative hemorrhage were similar in both groups [31].

In their meta-analysis of 7 studies comparing outcomes of tonsillectomies performed using *all* vessel sealing systems (including thermal welding, LigaSure, and the BiClamp device) with tonsillectomies performed using conventional technique, Alexiou et al. found that operative time was shorter and perioperative bleeding significantly less in the Vessel Sealing System group. They also found that vessel sealing yielded significantly less postoperative bleeding and pain as compared to conventional techniques [27]. This meta-analysis, however, was limited because of significant methodological heterogeneity among the studies, as well as the fact that the analysis pooled studies of 3 different devices [27].

COST

As demonstrated above, there are a variety of options in today's world for how to perform tonsillectomy or T&A, each with its own advantages and disadvantages. Though a full discussion regarding cost analysis is beyond the scope of this chapter, it is important to note that there is significant variation in adenotonsillectomy hospital costs per case among individual surgeons [32]. As Meier et al. (2015) discuss in their study of 26,626 patients who underwent same-day adenotonsillectomy (alone), there are dramatic differences among surgeons' mean cost per case, suggesting that individual providers bear personal responsibility for much of the cost variations of the procedure. The authors found that intrahospital variation among surgeons was impacted by the time in the operating room and the instruments each surgeon chose. The data suggest that increased costs do not necessarily equate to improved outcomes as measured by postsurgical complications. In fact, in this particular study, the authors found that the surgeons with higher mean costs tended also to have higher complication rates, although the difference was not statistically significant [32].

SUMMARY

There are many factors to consider when choosing the technique for tonsillectomy or T&A. This chapter provides a general summary of these, as well as the advantages and disadvantages of not only each instrument, but also those of extracapsular versus intracapsular tonsillectomy. As we move forward, overall cost considerations will undoubtedly influence the choice of technique.

Chapter 169

COBLATION INTRACAPSULAR TONSILLECTOMY

Sophie Shay, MD and Nina L. Shapiro, MD

Department of Head and Neck Surgery, David Geffen School of Medicine,
University of California Los Angeles, Los Angeles, CA, US

INTRODUCTION

Coblation® technology is a relatively new instrumentation for tonsillectomy. Since the early 2000's, it has gained increased acceptance and use amongst otolaryngologists. Given its potential for decreased postoperative morbidity, decreased postoperative pain, faster return to a normal diet, and faster return to normal activity, more surgeons have considered utilization of this technique. The primary method for tonsillectomy with the coblation wand has been that of extracapsular tonsillectomy, with perioperative bleeding rates similar to those of other techniques published in the literature [1]. More recent development of wands with larger contact surfaces, enabling tissue ablation, has led to use of this technique for intracapsular tonsillectomy.

Coblation® uses a radiofrequency bipolar electrical current to ablate and coagulate soft tissue at a frequency lower than standard bipolar diathermy, thus avoiding thermal injury. The device conducts the current through normal saline located between the device tip and soft tissue, whereby the saline is converted into an ionized sodium plasma layer. The sodium ions are capable of breaking down molecular and intracellular bonds in the tissue, thereby vaporizing the tissue at temperatures between 40-70° C. Irrigation of saline also reduces the amount of thermal energy transmitted to surrounding soft tissues, thus decreasing the amount of postoperative pain [6–8].

In recent years, intracapsular tonsillectomy has become more popular, with increasing evidence that near-complete removal of pharyngeal tonsils, leaving the lateral-most portion of the capsule intact is associated with reduced rates of bleeding and postoperative pain, while having similar outcomes in eliminating obstructive tissue [2]. The trend towards performing intracapsular tonsillectomy for obstructive sleep apnea and sleep disordered breathing has been seen in European countries such as Austria, Sweden, and the United Kingdom [12]. Hultcranz et al reported a 0.8% postoperative bleeding rate for intracapsular tonsillectomy,

compared to 3.4% for extracapsular tonsillectomy [15]. Without showing any differences in obstructive sleep apnea symptoms, this study also reported decreased rates of readmission, number of days using analgesics, and nosocomial infections at 6-months follow-up. Zhang et al reported a 6.1% rate of tonsillar regrowth with 5 year follow-up, suggesting a low rate of tonsillar tissue regrowth following intracapsular tonsillectomy [11].

Many advocate for the use of coblation in performing intracapsular tonsillectomy as a method to further decrease perioperative morbidity, though the literature demonstrating this technique as superior to more traditional methods remains controversial [2, 7, 13, 14, 16, 17]. A randomized, blinded controlled study by Chang reported that by postoperative days 5-6, patients who had coblation intracapsular tonsillectomy had significantly better pain control, diet resumption, and normal activity level compared to coblation total tonsillectomy [17]. Using the Swedish National Registry for Tonsil Surgery, Sunnergren et al found a 1.2% postoperative bleeding rate requiring readmission, with a mean for 4.2 days using analgesics amongst 1,676 patients [13]. In a study of 415 patients, Duarte et al reported that patients who had coblation intracapsular tonsillectomy resumed normal diets 5.4 days after surgery, compared to 8.0 days for those who underwent coblation extracapsular tonsillectomy ($p = 0.022$), and had better postoperative pain control [16]. When adenoidectomy was performed in conjunction with coblation intracapsular tonsillectomy compared to extracapsular tonsillectomy, Babademez et al (2016) reported decreased rates of symptomatic and subclinical adenoid regrowth [18].

Coblation® has been shown to be an effective and safe surgical tool for intracapsular tonsillectomy. In particular, coblation intracapsular tonsillectomy may be associated with lower rates of postoperative pain, decreased postoperative bleeding, faster return to normal activity, and quicker return to a normal diet. Coblation intracapsular tonsillectomy represents an important technique in the surgical management of adenotonsillar hypertrophy.

COBLATION INTRACAPSULAR TONSILLECTOMY ADENOIDECTOMY TECHNIQUE

For performance of intracapsular tonsillectomy/adenoidectomy using a Coblation® instrument, the PROCISE MAX® wand is recommended. This provides a broader tip, in order to adequately ablate the bulky lymphoid tissue. The larger tip also minimizes intraoperative plugging of the wand's contact screen, and allows for better intraoperative coagulation.

The patient is placed in the standard Rose position and intubated with an oral RAE tube. A Crow-Davis mouth gag is placed and suspended. The Coblation® device is set on a setting of '7' for coblation ('cut' equivalent) and '3' for coagulation. A 1-liter intravenous fluid bag of saline is hung for irrigation, and the suction is attached to a standard suction device on continuous suction when the device pedal is activated. (VIDEO X) The wand is placed first on the right tonsil, and in a 'painting' motion, the tonsil tissue is ablated (on 'coblate 7') until the lymphoid tissue abutting the fossa is visualized. The defect should look concave. In using the coblate function, one needs to very lightly touch the tissue to create an ablation effect. The wand is intermittently used to coagulate the small intra-tonsillar vessels throughout the procedure. The entire base of the thin layer of capsule at the fossa is then coagulated with the

coblation wand on ‘coagulate 3’. Irrigation flow needs to be clear, as does suctioning, in order for the wand to function. When using the coagulation function, the wand screen is placed flatly on the tissue. Gentle pressure can be given to coagulate, as the coagulation function is relatively weak compared to a similarly designed suction electrocautery device. As the maximum temperature of the wand is 70 degrees Celsius (as opposed to 450 degrees Fahrenheit for an electrocautery wand), there is a significantly lower risk of deep tissue and/or vessel injury when coagulating. The left tonsil is ablated in the same fashion as the right. No other instruments are needed during the tonsillectomy.

For the coblation adenoidectomy, a single red-Robinson catheter is placed into the right nasal cavity, grasped intraorally with a curved hemostat, and used as a palatal elevator. Under indirect visualization with a laryngeal mirror, the adenoidectomy is performed. The PROCISE MAX ® wand is bent slightly, in order to access the adenoids. The wand should take on a C-shape. Bending the distal end of the wand into an L-shape will lead to plugging of the tip. The wand is then utilized to ablate the adenoids, beginning at the left choana, and continuously moving first laterally, and then inferiorly, also in a ‘painting’ motion, until Passavant’s ridge is reached. As with the tonsillectomy, coagulation is used intermittently as needed, as well as at the conclusion of the adenoidectomy for any continued bleeding.

Especially in children with large tonsils and adenoids, the wand may become plugged with lymphoid tissue. It will not function when plugged, as both the suction and the irrigation need to be continuous when the coblation instrument is used. To avoid plugging, the wand is placed in a basin of saline, and the coblation pedal is activated while moving the wand in and out of the saline. If this does not clear the tip, temporary disconnection of the suction tubing, followed by flushing the wand with a 10cc syringe of saline will clear the tip.

Coblation® intracapsular tonsillectomy/adenoidectomy is an extremely safe, effective technique, especially in patients undergoing the procedure for chronic obstructive symptoms. The procedure requires only one instrument, whereby adjuvant need for electrocautery devices, bipolar instruments, or sutures are rarely, if ever, necessary. As with most new technologies and techniques, there is a steep ‘learning curve’ when first performing this technique. The primary challenge is the surgeon’s sense of how much, or how little, direct tissue contact is needed to maximize ablation, minimize wand plugging, and maximize coagulation, all while maintaining appropriate visualization and tissue planes. Once this comfort level is achieved, the technique is easily reproducible, with extremely consistent results in patient outcomes.

Chapter 170

THE RESULTS OF INTRACAPSULAR VS. EXTRACAPSULAR TONSILLECTOMY

Benjamin J. Rubinstein, MD and Craig S. Derkay, MD

Department of Otolaryngology, Eastern Virginia Medical School
Norfolk, VA, US

ABSTRACT

Intracapsular tonsillectomy and traditional extracapsular tonsillectomy are both efficacious for treatment of pediatric obstructive sleep apnea (OSA) associated with adenotonsillar hypertrophy. Preliminary research suggests a role for intracapsular techniques in recurrent tonsillitis, but data is limited and extracapsular tonsillectomy remains predominant. With intracapsular tonsillectomy, pediatric patients recover faster, use less pain medication, and have a lower risk of dehydration and hemorrhage postoperatively. Extracapsular tonsillectomy is superior in terms of regrowth rates, though reoperation after intracapsular tonsillectomy is rare. Intracapsular tonsillectomy has the potential to reduce the financial footprint of tonsil surgery. The benefits of intracapsular tonsillectomy have been described in well-designed clinical trials and meta analyses.

INTRODUCTION

Intracapsular tonsillectomy and traditional electrocautery tonsillectomy have both proven efficacious for treatment of pediatric obstructive sleep apnea (OSA) associated with adenotonsillar hypertrophy [1-6]. While electrocautery tonsillectomy is superior in terms of regrowth rates, it is associated with not-insignificant rates of postoperative hemorrhage and pain with associated dehydration [1, 7-10]. The 21st century has seen the adoption of various technologies to replace cold steel and electrocautery extracapsular tonsillectomy without significant improvement in postoperative outcomes [10]. Intracapsular tonsillectomy has increasingly been investigated as an alternative to extracapsular tonsillectomy to reduce pain, hemorrhage, and hospital readmission. With intracapsular tonsillectomy, pediatric patients

recover faster, use less pain medication, and have a lower risk of dehydration and hemorrhage postoperatively. The benefits of intracapsular tonsillectomy have been described in well-designed clinical trials and meta analyses [7, 11-13].

POSTOPERATIVE PAIN

Otolaryngologists have become accustomed to counseling their patients' families that "the next two weeks are going to be tough." Despite scheduled or PRN dosing of narcotic and/or non-narcotic pain medications, children continue to experience moderate pain following total tonsillectomy. Postoperative regimens are also hampered by caregiver non-compliance. Given the unreliable metabolism of acetaminophen/codeine and its lack of superiority over acetaminophen alone, codeine has fallen out of favor.

Systematic reviews have suggested the safety of non-steroidal anti-inflammatory drugs (NSAIDs), but uncertainty remains with updated analyses unable to exclude an increased risk of bleeding [8, 14, 15]. The most recent Cochrane review on the matter noted a "non-significant increase in the risk of bleeding requiring surgical intervention," with an odds ratio of 1.69 and a confidence interval of 0.71 to 4.01. Bleeding events not requiring surgical intervention were not significantly increased in their analysis [15]. Another meta-analysis in the same year that included 36 randomized controlled trials found no increased risk of bleeding after or during tonsillectomy when NSAIDs were utilized [16]. As individual institutions have examined their own experience with NSAIDs, the debate has continued regarding the safety of NSAIDs relative to narcotics [17, 18].

Intracapsular tonsillectomy results in significantly less postoperative pain than total tonsillectomy. Children stop using pain medication 2.5 days earlier when randomized to microdebrider intracapsular tonsillectomy. These children are 2.5 times more likely to be off pain medication at one week, and 39% take their last dose of pain medication at postoperative day 3 versus 18% in the electrocautery tonsillectomy group [19]. In a randomized, double-blind, paired control study, Lister removed one tonsil by electrocautery and the contralateral by microdebrider intracapsular tonsillectomy in each patient. Children reported significantly less pain on the tonsillotomy side for the first 9 postoperative days. While 80% of the children reported otalgia, it was always unilateral and on the side of the electrocautery tonsillectomy [20]. The benefit of reduced postoperative pain with intracapsular tonsillectomy holds true when using the coblator [21, 22] or bipolar scissors [23]. The reduced perioperative morbidity is related to surgical technique, rather than the instrument, likely secondary to preservation of a biologic dressing over the pharyngeal musculature and decreased thermal injury to the tissues [9, 10, 19, 20, 23].

POSTOPERATIVE RECOVERY

Reduced postoperative discomfort in children manifests as a quicker return to normal activity and normal diet. Chang randomized children to intracapsular versus subcapsular coblation and reported improved diet and activity levels in intracapsular patients throughout the postoperative course [22]. Patients return to a normal diet and activity level 1.5-2.5 days

earlier when the intracapsular techniques are compared to extracapsular tonsillectomy [21]. The addition of QuikClot for hemostasis allows decreased cauterization, and time to full recovery is inversely related to total intraoperative cauterization. Patients treated with this intracapsular technique using QuikClot experience cessation of narcotic use in 3 days and complete recovery (normal diet, normal activity, and no narcotics) in 4.5 days [24]. Meta-analysis has shown that even when reviewing only randomized clinical trials, children use less pain medication (2.5 days) and recover to normal diet faster (2.15 days) with intracapsular techniques [7].

When children recover faster with less discomfort, families can return to their normal lifestyle and productivity without distress. When considering the success of a tonsillectomy, it is essential to consider the entire experience of the postoperative course, including any unplanned stressors. Imagine the frustrating process of struggling with a child who arrives at a point of dehydration requiring phone calls to the office, emergency department visits, and possible readmission. Schmidt reviewed data from 2944 patients and identified a rate of ER evaluation for postoperative pain or dehydration of 3% for intracapsular tonsillectomy compared with 5.4% for total tonsillectomy [25]. Other retrospective studies have similarly favored the intracapsular technique due to lower rates of re-admission for dehydration at only 0.4%-1.3% [26, 27]. At Columbia/Cornell, the intracapsular group had a 0.3% rate of readmission or ED visit versus 8.3% in the total tonsillectomy group [28]. While some studies find readmission rates to be similar between the two techniques, data has not been published to support lower readmission rates in total tonsillectomy patients [7]. The psychological and financial impact of these postoperative events on families can be surmised but has yet to be studied.

POSTOPERATIVE HEMORRHAGE

Intracapsular tonsillectomy carries a lower rate of postoperative hemorrhage than total tonsillectomy. Francis found that pooled bleeding rates were 1.5% for partial tonsillectomy versus 4.2% for total tonsillectomy, though their meta-analysis could not “prove” superiority of partial tonsillectomy. Children having surgery for obstruction were less likely to bleed than those with recurrent infection, and this effect was predominantly driven by late bleeds (1.9 vs. 3.9%). Analysis of partial tonsillectomy in the setting of surgery for recurrent tonsillitis was limited by small sample size [29]. Schmidt’s retrospective review showed a 1.5% vs. 5.3% bleeding rate for pediatric intracapsular vs. electrocautery tonsillectomy in patients with recurrent tonsillitis. This same review showed a smaller, but significant, difference in post-tonsillectomy bleed rates between patients undergoing surgery for obstruction using intracapsular vs. extracapsular techniques (1.1% vs. 2.4% respectively) [25].

Currently unpublished data covering 4395 tonsillectomies for any indication at a tertiary children’s hospital found combined bleeding rates (managed in the ED or in the OR) of 2.6%, 4.3%, and 0.5% for electrocautery tonsillectomy, coblation tonsillectomy, and microdebrider intracapsular tonsillectomy respectively. Rates of hemorrhage requiring return to the OR were dramatically different at 1.2% (electrocautery), 1.6% (coblation), and 0.2% (microdebrider). Of children experiencing bleeding, the surgical indication was obstruction in 61% and recurrent tonsillitis (or both) in 39% [30].

Extensive reviews have echoed the improved safety profile of intracapsular technique and note its increasing utilization. A large review of randomized controlled trials found that intracapsular tonsillectomy for obstruction is associated with a 0.7% rate of late hemorrhage compared with 2% in total tonsillectomy for obstruction [11-13]. A recent retrospective review also showed lower bleeding rates for intracapsular (0.2%) vs. total tonsillectomy (2.9% total, 1.6% return to OR), though it should be noted that intracapsular patients tended to be younger and have a lower BMI [1]. Given the low incidence of post tonsillectomy hemorrhages overall and variations in both reporting and surgical technique, smaller prospective trials often do not reveal these benefits. In the age of decreasing postoperative antibiotics and more liberal use of NSAIDs, these small differences may become more pronounced [31].

Caring for a child with a post-tonsillectomy bleed is an unforgettable experience for the families and the provider. The experience of a life-threatening complication for the parents and child usually includes a trip to the ER along with uncomfortable interventions. Research to date has not specifically investigated the impact on quality of life of a post tonsillectomy bleed. In the debate between various tonsillectomy techniques, researchers should use caution when solely comparing rates of post-tonsillectomy bleeding with those of tonsillar regrowth or recurrent sleep apnea in assessing outcomes.

TREATMENT EFFICACY AND REGROWTH RATES

Intracapsular tonsillectomy is as efficacious as total tonsillectomy for treating obstruction and is durable in the vast majority of patients. In his large retrospective review, Chang found that intracapsular patients had a statistically similar average change in AHI compared to total tonsillectomy patients ($5.6\% \pm 8.6\%$ and $8.6\% \pm 12.9\%$, respectively). A similar percentage of patients showed improvement in AHI in both groups. In this study, 2.0% of patients underwent surgery for tonsillar regrowth [1].

Mukhatiyar showed no difference in treatment failure between intracapsular and extracapsular techniques as measured by pre and post-operative polysomnogram. In both studies, children were older and more obese in the extracapsular groups. It is interesting to note that the Mukhatiyar study suggests that intracapsular tonsillectomy tends to be recommended by practitioners to younger patients because of their intrinsically higher risk of pain and bleeding. This recommendation seems contrary to the understanding that older children tend to be at a higher risk for post tonsillectomy hemorrhage [27, 32] and the risks of regrowth tend to be higher in the younger patients [33]. Mukhatiyar suggests the superiority of extracapsular technique in the obese asthmatic population, however this assertion was based on analysis of a very small sample size and did not hold true for asthma or obesity independently. Effectiveness of intracapsular technique has been demonstrated in children with severe obstructive sleep apnea as measured by polysomnogram with the average obstructive apnea hypopnea index decreasing from 25.5 to 3.9 [34]. The reduction of symptoms and resolution of sleep apnea has been consistently demonstrated by retrospective and prospective trials alike [3-6].

Regrowth rates in intracapsular tonsillectomy are low, estimated at 0.5%-6.1%, with a low proportion of these patients needing reoperation for infection or obstruction [26, 35, 36].

Chang identified 2% of patients with tonsillar regrowth that resulted in a return to the OR for secondary tonsillectomy. Sorin studied 278 patients and identified a 3.2% rate of regrowth with snoring, though only 0.7% required secondary tonsillectomy due to the return of OSA [35].

Little research has focused on the relative efficacy of intracapsular tonsillectomy for recurrent tonsillitis. Schmidt retrospectively reviewed 116 patients who underwent either extracapsular or intracapsular tonsillectomy for recurrent tonsillitis and did not show any difference in the number of patients with at least one postoperative sore throat infection in the first year of post-operative observation (14% vs. 16% respectively) [37]. For all patients undergoing intracapsular or total tonsillectomy, randomized trials have suggested no difference in the rate of tonsillitis, though follow-up duration is limited [11]. It should be noted that patients with total tonsillectomy are not free from visible regrowth, tonsillitis, or peritonsillar abscess, though certainly the rates of regrowth are substantially lower [13].

There has been concern that younger patients might be more likely to need reoperation due to regrowth or tonsillitis in the future [13, 33]. This argument must be balanced against considerations that younger populations are also at a higher risk for dehydration and are particularly likely to benefit from a less morbid procedure. For this reason, some institutions are favoring intracapsular tonsillectomy for their younger population [2]. In fact, some centers are successfully treating patients younger than 3 years old in an ambulatory fashion without complications using intracapsular surgery (provided they have adequate supervision, <30 minute access to a hospital, and an uneventful post-anesthesia care unit course) [38]. Increasingly, tonsil surgery is being performed in an ambulatory fashion, even when guidelines would suggest that patients be admitted due to age or comorbidities [39]. Surgeons shoulder the responsibility to offer the technique that offers the best outcome for the majority of patients and to reach a plan along with parents through a shared decision making process.

COST CONSIDERATIONS

In the current medical environment, cost containment is paramount, and intracapsular tonsillectomy offers an opportunity to reduce the financial footprint. In a prospective, randomized, double blinded study, microdebrider intracapsular tonsillectomy was more cost effective (\$2,205) than both intracapsular coblation (\$2,837) and electrocautery tonsillectomy (\$2,825). Decreased cost was driven by the shorter operative time for bilateral tonsillectomy with the microdebrider (16 minutes) (cautery = 21 min, coblation = 20 min). The microdebrider (\$100) was also less expensive than the coblation wand (\$200) [21]. Some institutions have seen slightly increased surgical time for the microdebrider, but it is anticipated that this difference may decrease with experience [40]. At my institution, surgical time (mouth gag in till mouth gag out) for tonsillectomy and adenoidectomy averages 19.8 minutes with the microdebrider [24].

Reduction in PACU time, ER visits, unplanned re-admissions, narcotic use, and postoperative complications further contribute to potential cost savings. For example, Stucken demonstrated a decrease in PACU time of 82 minutes for intracapsular tonsillectomy patients [19, 28]. Intracapsular tonsillectomy is proving safe to perform in patients younger than 3 years old in an ambulatory fashion without any increased risk of dehydration or readmission

compared to older children [38]. It would seem logical that future research may uncover previously unmeasured financial benefits for intracapsular tonsillectomy in which caregivers are able to return to work sooner and are resting better at night, allowing for a more productive workday.

CONCLUDING THOUGHTS

Intracapsular tonsillectomy has been revived as an effective treatment that reduces cost and morbidity without sacrificing efficacy. Quality of life and return to productivity in the families should be factored strongly into our decision-making regarding surgery. Particularly in an age where observation is emerging as a reasonable alternative to tonsillectomy, we need to be certain about our goals for surgery [41, 42]. The more frequent significant complications associated with total tonsillectomy include readmission due to dehydration and hemorrhage. These complications occur in an emergent and stressful fashion, which is both financially and psychologically costly for patients, families, and physicians.

The principal drawback of intracapsular tonsillectomy, regrowth and the potential for reoperation, occurs in the setting of routine outpatient follow-up and occasionally results in ambulatory surgery. Certainly, this scenario could cause a degree of suffering for the child and psychologic distress for the family, but not in a fashion consistent with the potential for post-traumatic stress. Further research will hopefully elucidate the role of intracapsular tonsillectomy for recurrent tonsillitis, and prospective studies will help solidify our understanding of long-term complication rates between the two techniques.

Chapter 171

THE MANAGEMENT OF POST-TONSILLECTOMY PAIN IN CHILDREN

David E. Tunkel, MD and Grace X. Tan, MD

Department of Otolaryngology, Head and Neck Surgery
Johns Hopkins University School of Medicine, Baltimore, MD, US

ABSTRACT

Pain management for children following tonsillectomy is challenging and controversial, particularly concerning the use of opioids and non-steroidal anti-inflammatory drugs (NSAIDs). We discuss a variety of pharmacologic and non-pharmacologic interventions that can be used pre-, intra-, and post-operatively for analgesia and review the evidence for their efficacy and side effects. We focus on the technique of partial intracapsular tonsillectomy and its benefits in reducing post-tonsillectomy pain.

Keywords: tonsillectomy, pain, analgesia, opioids, obstructive sleep apnea (OSA)

INTRODUCTION

Tonsillectomy, with or without adenoidectomy, is the second most common procedure performed in children in the United States (US) [1]. Most patients undergo tonsillectomy as an ambulatory procedure, though some may require a one-night hospitalization. Pain after tonsillectomy is well-characterized, lasting 7-14 days and worsening over the first post-operative week. Hence, the majority of postoperative pain management occurs in the home setting. The challenges of effective post-tonsillectomy analgesia is reflected by the numerous pharmacologic and non-pharmacologic approaches that have been studied, in efforts to safely improve comfort after this procedure.

Poor pain control leads to parental anxiety, clinic calls, emergency room visits, and readmissions. Recent studies have shown that the common reasons for unplanned post-tonsillectomy encounters in emergency departments include uncontrolled pain, dehydration,

nausea, respiratory issues, and bleeding—all of which may be related to pain and the methods used for analgesia [2, 3]. Additionally, tonsillectomy surgery is performed most commonly for treatment of children with sleep disordered breathing and obstructive sleep apnea syndrome (OSAS). Children with such sleep-related breathing disturbances have unique risks using the most common postoperative analgesics.

Many factors are at play in adequate post-tonsillectomy pain control. They include: parental/caregiver factors, such as their socioeconomic status, race, cultural background, ability to assess pain, and medical literacy; child/patient factors, such as anxiety levels, and refusal or inability to take medications due to pain; medication factors, such as their palatability, strength, type, and adverse effects; as well as system factors, such as access to analgesics and the adequacy of discharge instructions [4, 5, 6]. Surgical techniques used for tonsillectomy, such as “hot” dissection versus “cold” dissection techniques, or total (extracapsular) versus partial (intracapsular) methods of removal, can also affect the severity and duration of postoperative pain [7, 8].

The main focus for post-tonsillectomy analgesia has been the use of medications, namely acetaminophen, opioids, and non-steroidal anti-inflammatory agents (NSAIDs). We will discuss commonly used medications such as ibuprofen and other NSAIDs, where their effect on postoperative bleeding are still debated, and opioids, where focus has been on postoperative respiratory depression that may be related to pharmacogenomics. This chapter will discuss contemporary issues with commonly used pharmacologic agents and will also discuss non-pharmacologic interventions that may aid in pain management. Often, multimodal approaches may be needed to minimize opioid requirements [9]. We will also discuss some of the technical details of tonsillectomy that may reduce pain, with a focus on the powered intracapsular tonsillectomy/adenoidectomy approach. While the term *tonsillectomy* is used throughout the chapter, we recognize that tonsillectomy is performed along with adenoidectomy in most children—the discussion in this chapter applies to *adenotonsillectomy* as well.

PAIN MANAGEMENT WITH MEDICATIONS: CONTEMPORARY ISSUES

Acetaminophen

Acetaminophen, alone or in combination, is perhaps the most commonly used analgesic administered after tonsillectomy in children. Acetaminophen alone may be inadequate for pain control; in fact, many studies of pain management show breakthrough pain in a substantial subset of children even with combinations of medications [10]. Interestingly, one randomized study comparing acetaminophen with acetaminophen/codeine found no difference in pain control after tonsillectomy in children [11]. The potential for hepatic injury exists with the use of acetaminophen, particularly in high sustained doses [12].

Narcotics/Opioids

Codeine (in combination with acetaminophen) was likely the most frequently prescribed post-tonsillectomy analgesic for children until a 2009 report of a codeine-related post-tonsillectomy death associated with an ultra-rapid metabolizer genotype made physicians question its usage. After reports of similar cases, an FDA investigation identified 13 pediatric deaths and 3 overdoses associated with codeine between 1969 and 2012—8 of which were in tonsillectomy patients [13]. Many of the affected children were ultra-rapid metabolizers of codeine—they carried a genotypic variation of the enzyme cytochrome P450 2D6 pathway, causing rapid conversion of codeine to high levels of the active morphine metabolite, with resultant respiratory depression. Because children with OSAS are more sensitive to the respiratory depressant effects of narcotics than children without such sleep-related airway disease [14], these adverse events are most likely to occur in young children with OSAS.

In 2013, a Boxed Warning and Contraindication was placed on the use of codeine after tonsillectomy and/or adenoidectomy in children. This Boxed Warning and Contraindication applies to all children undergoing tonsillectomy, as it is impractical and costly to identify children at-risk from either the ultra-rapid metabolizer genotype or from severe sleep apnea prior to surgery [15]. It is notable that codeine use is also limited by a sizeable subset of patients who cannot metabolize this drug to the active form, resulting in poor analgesic effect.

Additionally, many opioids, including hydrocodone and tramadol, share the same cytochrome P450 CYP2D6 metabolic pathway as codeine. Despite this, hydrocodone is becoming more widely used as an alternative to codeine. Tramadol has been suggested as an alternative to codeine, as it may cause less sedation compared to codeine, with similar analgesic effects [16, 17]. However, a recent report of respiratory depression in a CYP450 2D6 ultra-rapid metabolizer led the FDA to announce a review of tramadol use in children [18, 19].

Oxycodone and morphine, on the other hand, are not metabolized by the cytochrome P450 2D6 pathway [8] and have been proposed as alternatives to codeine. However, when oral morphine was compared to ibuprofen in a recent study, it caused far greater numbers of respiratory events in the immediate postoperative period [20]. Another study of oral morphine given as a “rescue analgesic” in addition to acetaminophen and ibuprofen showed no measurable benefit [21].

Use of opioids other than codeine for post-tonsillectomy pain may still have risk, particularly for children with OSAS. Opioids have been shown to depress ventilation and precipitate apnea to a greater extent in children with OSAS compared to controls [22]. Furthermore, children with OSAS are reported to have a reduced opioid requirement to achieve the same level of post-operative analgesia. Brown et al. hypothesized that recurrent hypoxemia found in severe OSAS may lead to up-regulation of central opioid receptors, thereby leading to an increased response to smaller doses of opioids [14].

Hence, the issues with opioid-based analgesia after tonsillectomy in children is not simply one of genotypes and metabolic differences. Although pharmacogenomic profiling of patients undergoing surgery could help stratify risk, the severity of obstructive sleep apnea, the age of the child, the presence of obesity or other co-morbid conditions, and the ability to accurately dose and administer medications all play a role in the decision to safely use opioids. Clinicians should assess the risk of respiratory compromise in children undergoing tonsillectomy to guide opioid use, narcotic dosage, and duration/location of postoperative

monitoring. Additionally, the comparative efficacy of analgesia with other non-opioid classes of medications—as discussed later in this chapter—should be understood as we provide alternatives to the long-used codeine-based regimens.

NSAIDs

Non-steroidal anti-inflammatory drugs (NSAIDs), most frequently ibuprofen, have been extensively studied, and are now commonly used, as an effective method to relieve post-tonsillectomy pain without opioids. Ibuprofen has been shown to be effective for post-tonsillectomy analgesia in a number of studies over the past 20 years. Despite this, many providers have been, and some still are, hesitant to prescribe NSAIDs because of concerns that such medications may increase the frequency and severity of post-tonsillectomy bleeding [23]. However, two large systematic reviews of studies investigating the use of NSAIDs post-tonsillectomy failed to show significant difference in rates of bleeding between NSAIDs, placebos, and opioids, including rates of bleeding requiring admission or surgery [24, 25]. Additionally, when compared to opioids, ibuprofen-based analgesia has the benefit of decreased post-operative nausea and vomiting [25, 26]. Furthermore, in the aforementioned trial of oral morphine versus ibuprofen after tonsillectomy, ibuprofen proved equally effective compared to morphine in treating post-tonsillectomy pain, with fewer respiratory issues [20].

The increased use of ibuprofen for pain management after the Boxed Warning for codeine has led to single-institution comparison studies of bleeding after tonsillectomy with ibuprofen or codeine-based regimens. Mattos et al. in Pittsburgh found no increased bleeding with ibuprofen use, although the rate of “any bleeding” was over 8% with or without ibuprofen [27]. Bedwell et al. reported a series of 666 children after tonsillectomy, and found no difference in emergency room utilization between ibuprofen and codeine regimens [28]. While the ibuprofen group in this study had a statistically non-significant trend toward more bleeds (3.5% vs. 1.7%), there was no observed difference in bleeds that required return to the operating room. Most recently, Pfaff et al. studied over 6000 children after tonsillectomy, during a period when codeine use stopped and ibuprofen use started [29]. The number of admissions and/or operations for bleeding after surgery remained unchanged.

Ketorolac deserves mention, as the American Academy of Otolaryngology-Head and Neck Surgery *Clinical Practice Guideline:Tonsillectomy in Children* specifically discusses avoidance of ketorolac because of postoperative bleed rates of 4.4% to 18% associated with this drug [30]. However, this increased risk of bleeding with ketorolac appears to be principally in adults after tonsillectomy, rather than in children [31].

The debate about NSAID use will continue, as experienced clinicians disagree and studies have conflicting results. Liu et al. reviewed a regimen of alternating doses of acetaminophen and ibuprofen as an effective means for post-tonsillectomy analgesia, with 90.4% of patients reporting adequate pain control in their retrospective study [32]. However, Merry et al. found that this regimen of combined acetaminophen and ibuprofen was not superior in analgesia to either medication given alone [33]. Perhaps relevant to this text about powered intracapsular tonsillectomy, DeSouza et al. found increased primary (1.6% vs. 0.5%) and secondary (3.8% vs 1.1%) bleeding in children after powered intracapsular tonsillectomy, when ibuprofen-based regimens were compared with opioids [34].

Other Medications

A variety of medications have been suggested or studied as adjuncts or alternatives to acetaminophen, opioids, and NSAIDs. These include: preoperative administration of oral montelukast [35]; intra-operative intravenous dexamethasone [36]; postoperative oral steroids; perioperative ketamine in subcutaneous, intravenous, and spray formulations [37, 38, 39]; clonidine [40]; and oral pregabalin [41]. COX-2 inhibitors such as celecoxib may reduce inflammation and pain without potential bleeding risk, but a recent study of this medication did not show a sustained reduction of pain after tonsillectomy [42]. While benefits have been demonstrated for some of these drugs, only additional study and experience will lead to broader acceptance and use for children after tonsillectomy.

Operative Adjuncts

In some studies, intra-operatively, pre-incisional peritonsillar infiltration of local anesthetic and/or steroids [43, 44] have been shown to be effective in producing post-tonsillectomy analgesia. Treating the wound bed with hyaluronic acid [45] and cold water [46] intra-operatively may reduce pain. On the other hand, one recent study using polyglycolic acid sheeting to coat the tonsillar fossa found increased pain in treated adults [47]. Other non-pharmacologic methods include honey [48], acupuncture [49], and even imagery [50], which are low-risk and relatively well-tolerated. However, the studies of many of these methods are heterogeneous, with some demonstrating conflicting results with regard to pain reduction [51].

Parental Education

As post-tonsillectomy pain control is largely managed by the child's caregiver in the outpatient setting, it is crucial that the caregiver is educated on how to assess pain levels in their child at regular intervals. This can be done using behavioral pain scales [52], which are easy to use. However, while parents often do recognize pain, they do not give prescribed analgesics at the recommended doses for a variety of reasons [53]. One study showed that parents reported significant pain in their child during the first day at home after tonsillectomy, but 24% of these children received one dose or less of prescribed analgesics [54]. On the third postoperative day, 2/3 of parents observed significant pain in their child, but 41% of the children received one dose or less of analgesics.

Teaching done by nurses prior to discharge may reinforce the use of pharmacologic and non-pharmacologic options for pain control [55]. Nonetheless, the advantages of parental counseling are not straightforward. One recent study of home phone calls to caregivers made by nurses, four times over ten days after tonsillectomy, showed improved oral intake and adherence to analgesic use, but did not show any difference in pain intensity scores or use of health care resources [56]. Perhaps most importantly, in the event that opioids are administered in the post-operative setting, it is imperative that the caregiver is instructed on the risks of oversedation, as well as what to do if such an event occurs [57].

SURGICAL TECHNIQUES AND PAIN

A number of surgical techniques and instrumentation are available to perform tonsillectomy. Techniques can be divided into “cold” and “hot” dissection, to accomplish total or partial removal of the tonsils. Instrumentation includes cold dissection tools, monopolar and bipolar electrocautery, coblation devices, microdebriders, lasers, harmonic scalpel, argon plasma coagulation, and other devices [58].

A 2007 survey of pediatric otolaryngologists in the US showed that more than 50% use monopolar electrocautery for a total tonsillectomy. Use of cold dissection has declined from 7.0% to less than 1%, while coblation has risen in popularity from 0% to 15.9% over the 15 years leading up to 2007 [59].

Cold dissection appears to result in less postoperative pain compared to the use of monopolar electrocautery, but has fallen out of favor with many surgeons due to longer operative times and increased operative blood loss [60]. Coblation is a technique growing in popularity among surgeons [61]. It delivers bipolar radiofrequency through a saline field, with less heat generated compared to most other cautery techniques. While some reports of coblation tonsillectomy noted reduced postoperative pain, a Cochrane review concluded that there was insufficient evidence to show that coblation tonsillectomy is associated with reduced pain [62].

Partial Intracapsular Tonsillectomy

Partial tonsillectomy has been studied for the past 17 years, mainly since its introduction to the US by Peter Koltai and others [63]. Also called *tonsillotomy* or *intracapsular tonsillectomy*, this technique can be performed with microdebrider, laser, radiofrequency devices, bipolar scissors, or coblator, among other methods. Reduction of pain with this technique is expected, as the pharyngeal constrictor muscles and the tonsillar pillars are not violated. In fact, when compared with conventional tonsillectomy, powered intracapsular tonsillectomy with the microdebrider was shown to have reduced pain and reduced analgesic use at all measured points during the first 9+ days of recovery, with fewer days to return to a normal diet and activity [64]. A randomized blinded study, where microdebrider partial tonsillectomy was performed on one side and monopolar electrocautery tonsillectomy on the other, showed reduced throat pain and no otalgia on the microdebrider side during the first 9 days after surgery [65]. Similar benefits of reduced pain after intracapsular tonsillectomy were reported for partial tonsillectomy procedures performed with scissors [66], radiofrequency devices [67], carbon dioxide laser [68], and coblation [69].

After over two decades of partial tonsillectomy experience, several systematic reviews have been published that address intracapsular tonsillectomy. Acavedo et al. reviewed 33 studies that compared tonsillotomy with tonsillectomy, and found fewer cases of dehydration requiring medical care, reduced days of analgesic use, and a quicker return to normal diet with tonsillotomy [70]. Walton et al. reviewed 16 randomized controlled trials of intracapsular tonsillectomy versus conventional tonsillectomy, and found significantly reduced pain in 9 studies, no difference in pain in 4 studies, and several studies reporting improved pain without sufficient analysis of significance [71]. These authors found reduced

analgesic use and sooner return to a normal diet in the majority of the level-1 evidence they reviewed. A recent meta-analysis of tonsillotomy versus tonsillectomy by Wang et al. excluded all but ten studies, all ten from outside the US [72]. Only three studies addressed pain and these showed improved pain-free days with tonsillotomy.

OUR PROTOCOL

At the Johns Hopkins Bloomberg Children's Center, we prescribe acetaminophen 12.5mg/kg/dose to be given orally every 4 hours for 24 hours after surgery for all children, followed by the same dose of acetaminophen on an as needed basis, up to a maximum dose of 75mg/kg/day or 4g daily. For children without a specific contraindication to NSAID use, we also prescribe ibuprofen 10mg/kg/dose every 6 hours as needed for pain, to start in the first few hours after surgery. Opioids are not used for children less than 6 years of age or for any child scheduled for overnight observation after surgery. Postoperative overnight observation is scheduled almost exclusively for respiratory monitoring of children with clinical risk factors or documented severe obstructive sleep apnea. It is prudent that young children and/or children with such risk factors avoid opioids. For children over the age of 6 years undergoing surgery on an ambulatory basis, we prescribe acetaminophen with hydrocodone. We also prescribe acetaminophen combined with oxycodone or hydrocodone for most teenagers after tonsillectomy. For children with insufficient analgesia while hospitalized, opioids may be administered on a case by case basis, at reduced dose in a monitored setting, after discussion with senior surgical staff.

CONCLUSION

Pain management following tonsillectomy in children remains difficult. Approaches for effective analgesia as well as improved patient and caregiver satisfaction should combine pre-operative counseling about pain management options with the use of both pharmacologic and non-pharmacologic methods to reduce pain. While considerable debate continues about the use of opioids, otolaryngologists should understand the risks of opioids in young children with obstructive sleep disorders after tonsillectomy. Similar debate about bleeding risks with NSAID use persists, but a growing body of evidence supports efficacy and safety. We will learn more with continued use and study of these medications. Surgical technique can be modified to control pain as well, and the partial, or intracapsular, tonsillectomy techniques have been shown to reduce the severity and duration of pain after surgery.

Chapter 172

CONCLUSION AND FUTURE QUESTIONS

Max M. April*, MD

Department of Otolaryngology, New York University/Langone Medical Center,
New York, NY, US

ABSTRACT

This textbook has reviewed the last 16 years of the surgical procedure of tonsillectomy (IT vs ET) and relayed the results and complications of both procedures. Surgical technique has been described and captured on video for surgeons new to these options, as well as surgeons looking to advance their skills. This last chapter will address some of the still unanswered questions regarding intracapsular tonsillectomy.

Keywords: intracapsular tonsillectomy, partial tonsillectomy, tonsillotomy, subcapsular tonsillectomy, pediatric sleep apnea, sleep disordered breathing, tonsillectomy, and adenoidectomy

INTRODUCTION

The current literature has documented the efficacy and safety of IT, as well as the results in pediatric obstructive sleep apnea. We can now further evaluate the role of IT in children with recurrent tonsil infections, the need for admission of children under 3, the difference in anesthetic regimens, and the need for postoperative narcotic/ nonsteroidal usage. We will also evaluate the timing of PACU observation, the cost of the overall procedure, return to presurgical activity level, effect on swallowing, effect on voice, future lingual tonsil hypertrophy, and the potential effect on the incidence of obstructive sleep apnea in adults.

METHODS

Recurrent Tonsil Infections

The results of IT in children with recurrent tonsillitis was studied in 2009 [1]. Schmidt et al, found that 17 out of 117 children that underwent ET and 8 out of 49 children that had IT had at least one postoperative infection, numbers which were not statistically significant. As the surgical technique of IT has progressed, deeper dissection and more tonsil tissue removal has become common. In addition, it is important to electrocauterize the remaining tonsil tissue to eradicate any crypts and make the fossa as smooth as possible to decrease potential biofilm adherence.

We all realize that ET is not a perfect operation for recurrent streptococcal tonsillitis, but it has become our treatment recommendation when all else fails. Future studies are needed to determine whether IT results are similar to ET results for children with recurrent tonsillitis.

Another question is whether leaving some tonsil tissue after PITA can actually be protective in the future. Other centers have begun to study whether there are immunologic benefits after PITA.

Admission for Children under 3

Guidelines recommend that all children 3 and under be admitted to the hospital for tonsillectomies. These guidelines are based on studies of children under 3 years who underwent ET with the need for pain control and hydration. The age of 3 does seem arbitrary, but many medical centers require admission for children under the age of three who are having tonsil surgery. How many 4 or 5 year olds have been operated on as an outpatient, with these recommendations in mind, when they may be smaller or more medically frail than many 3 year olds?

In 2004, ambulatory PITA was first described [2]. We started using this ambulatory procedure because many parents would describe how little care and attention they needed to give to their children after PITA. Since 2002, there have been very few children admitted to the hospital as a planned admission after PITA. The reasons include underlying medical problems that need monitoring (cardiac, neurologic, pulmonary, and severe OSA) or a known bleeding disorder. To my knowledge, there have been no children scheduled for an outpatient PITA that had to be admitted because of either poor oral intake or pain control.

We have performed outpatient PITA on several children under 2. How then did we get to the guideline of children under 3, or those with an AHI over 10, needing to be admitted to the hospital for monitoring? These recommendations are based on a study that is unlikely to be repeated. At Johns Hopkins Hospital, in 1989, a child who was admitted to the pediatric floor postoperatively following a complete tonsillectomy died.

As part of the root cause analysis of this death, a study was undertaken at Johns Hopkins to perform a polysomnogram on each patient with the diagnosis of OSA the night following surgery in the Pediatric Intensive Care Unit (PICU) [3]. The need for intervention, which was mostly to awaken or reposition the child, was higher in children under 3 and those with an AHI over 10.

In retrospect, the use of narcotics was almost universal and most likely influenced the data. Further study should be undertaken that would monitor children under 3 or those with an AHI over 10 postoperatively after PITA or ET without narcotics. These findings would document whether or not interventions are truly needed for children under three with OSA who undergo PITA.

Anesthetic Considerations

There are many questions to answer with regard to the depth of anesthesia needed because of less pain experienced after extubation. Future studies should compare different regimens to determine the optimal recommendation for anesthesia depth. Could less intraoperative narcotic and sedative medication be used, potentially shortening the Post-Anesthesia Care Unit (PACU) stay further? Not going through the capsule vastly reduces the need for narcotic medication postoperatively, and the use of NSAIDs are not a problem. In addition, with concerns about multiple anesthetics in young children, IT may allow the otolaryngologist to address a moderate symptom, such as mild dysphagia or hyponasal speech. During the days of complete tonsillectomy, the potential complications would have prevented otolaryngologists from considering surgery for these more moderate symptoms.

Postoperative Pain Control without Narcotics

Since the FDA issued the black box warning against the use of codeine in the postoperative care of children after tonsillectomy, many otolaryngologists have had to make abrupt changes to their care of children and their postoperative instructions. These details are clearly reviewed in chapter 171 by Drs. Tan and Tunkel. We have not had a postoperative bleed after IT that has required a second anesthetic to control the bleeding. We suggest acetaminophen only for the day of surgery, but if that is not sufficient, it can be supplemented with ibuprofen. Without the fear of narcotic overdose, the safety of this procedure as an outpatient is enhanced. In addition, without narcotics, there are less gastroenterologic complaints. There is also less nausea and less constipation, both contributing to more oral intake of liquids and food and a smoother and quicker recovery.

Timing of PACU Observation

When ET was first documented to be a safe ambulatory procedure, the recommendations were that children be observed for 6 hours after surgery in the PACU. If there was inadequate oral intake or inadequate pain control, children would then be admitted. Over the years, this recommendation has been reduced to 3 to 4 hours in the PACU. Many centers have strict rules for this observation period. In a busy ambulatory surgery center, that requirement can limit the number of surgeries performed in a day as to allow enough PACU beds available. With PITA, our PACU observation time is no longer a set minimum. Each child must meet minimal requirements to be discharged and that time is most often between one and two

hours. Therefore PITA significantly shortens the recovery time needed in the PACU and the schedule for each day is not limited because by PACU space.

Overall Cost of Tonsil Surgery

We attempted to look at the cost differences between ET and IT, including the instrumentation cost [4]. In IT, each microdebrider blade adds approximately 90 dollars US, whereas in ET, a handheld cautery costs approximately 10 dollars US. Other costs start with the need for polysomnography (PSG) preoperatively. A study should be undertaken that examines the following: safety of surgery for patients that did or did not have a preoperative PSG; PACU time and medication usage; the cost of inpatient monitoring; when children can resume school and activity levels and the parents can resume work; visits to the ED for dehydration; pain control and bleeding; and future revision completion tonsillectomy. The emotional cost of an emergency procedure to control postoperative hemorrhage, let alone the need for a second anesthetic a week later, is difficult to quantify, but also must be considered.

Return to Presurgical Activity Level

Following ET, most children miss 7 to 10 days of school. Older patients may miss up to 2 weeks. That clearly affects the time when parents can return to work. Following PITA, we have found that most children miss 2 to 4 days of school. If surgery is scheduled for Thursday or Friday, most children return to school on Monday, with parents free to return to work.

The overall cost to society of children missing school and parents missing work is difficult to measure, but cutting this time by using IT, rather than ET, is sizeable.

In addition, most surgeons recommend no physical activity for 14 days after ET, even if the return to school is earlier. Our recommendation after PITA is that children may return to full activity including sports in 1 week.

Effect on Swallowing

Anecdotally, many children have improved swallowing following tonsillectomy and in fact have had dramatic dietary changes. This benefit should be compared between the two tonsillectomy procedures, both of which should be performed with adenoidectomy to control for the improved nasal airway and possible improved sense of smell and taste with improved nasal function. Many parents have described that their children with large tonsils have "marathon meals," meaning they spend a long time chewing their food. These children chew their food for a long time so they can swallow it past the large tonsils. Reducing the size of the tonsils can create a dramatic improvement in their eating.

In children who have neurologic issues such as cerebral palsy, ET could cause more harm than good with regard to swallowing.

Figure 1. This image depicts the scar tissue in the soft palate and lateral pharyngeal wall after ET.

Figure 2. In IT, the scar tissue shown in Figure 1 is avoided. This photograph is of a 5 year old one month after PITA. Note the improved palatal function and preservation of both the anterior and posterior pillar.

Not only is the recovery much more difficult with regard to pain control, but after ET, the swallowing and velopharyngeal closure can take months to improve. The scar tissue in the soft palate and lateral pharyngeal wall after ET (Figure 1) is avoided with IT (Figure 2). We have found much less swallowing difficulty after IT and quicker return to baseline. This issue could be studied in a prospective manner.

Effect on Voice

A discussion of postoperative voice includes two distinct different subjects. The first is hypernasality, and the second concerns professional (or almost professional) voice patients. A

study looking at nasal escape or other measurable qualities of hypernasality after both the ET and the IT procedures should be measured. It appears that the length of hypernasality after IT is much shorter than it is after ET. Prior to IT, it was common to see hypernasality for many months after ET. If hypernasality persisted for more than 6 months, a referral to speech therapy was warranted. Every year or two such a referral occurred. Since otolaryngologists began using IT, the majority of children no longer have hypernasality after 2 to 3 weeks, and I have not referred any patients for speech therapy for continued nasal escape of air. I suspect it is due to the improved velopharyngeal closure without scarring and improved pharyngeal muscle function. One study we considered was to measure nasal escape by nasometry at different postoperative intervals comparing ET to IT. The difficulty was the cooperation needed for nasometry. There may be an easier and more tolerated test to measure this nasal air escape after surgery.

When considering ET for those patients that use their voice professionally, there was always great concern whether pharyngeal scarring would affect vocal quality. There are many performers that may benefit medically from tonsil surgery that were not offered surgery, because of potential harm to their voice or vocal quality. When discussing IT with these patients, consideration of using a LMA for anesthesia is discussed, possibly reducing fear of intubation trauma. A study should be performed evaluating vocal function after IT versus vocal function after ET.

Overall Experience

How many times have you spoken to parents about tonsil surgery for their children, and the parents start the conversation with "my tonsillectomy was the worst experience of my childhood?" We have all heard these stories, which can certainly impact the decision making process when these parents are considering tonsillectomy for their child. An advantage of IT is that these discussions start out in a different way with the otolaryngologist saying, "Please forget your tonsillectomy experience. It is different now." That can be very reassuring for many parents.

Future Lingual Tonsil Hypertrophy

To this day, I have only performed lingual tonsillectomy in patients that had ET previously, and almost always these patients had ET at a young age. Could it be that ET at an early age promotes lingual tonsil hypertrophy or that leaving some tonsil tissue with IT reduces future lingual tonsil growth? I have discussed this with leaders in the field of surgery for sleep apnea in adults. In that population it would be very interesting to study how many of their patients that had lingual tonsillectomy as an adult had ET and at what age. In my experience, adolescents or young adults who had ET at a young age—often age 2 or 3 are those that present with lingual tonsil hypertrophy. Those patients should have PSG to document whether the lingual tonsils are causing obstruction, especially in the supine position.

Future Obstructive Sleep Apnea

Another topic that our colleagues that treat obstructive sleep apnea in adults could help us address is the contribution of ET or IT to Mallampati classification. It is apparent that those patients with class III or class IV are much more difficult to treat surgically. A retrospective study could look at what percentage of adult sleep apnea patients are in each category of the Mallampati classification.

It could be that scarring after ET reduces the height of the palate and its relative position to the tongue. The comparative study looking at patients after IT will have to wait several years to accumulate enough comparison data.

CONCLUSION

Since 2000, when I began performing IT, my practice has changed tremendously. There are several reasons, including increased patient and parental satisfaction. My own input of time, as well as the need to support patients and parents, has decreased. We do not have ancillary staff that responds to patient calls at night or on weekends. The amount of attention patients and parents need after IT is drastically reduced.

In my practice, I do not perform ET 2 weeks prior to a vacation or a meeting, so if there is a postoperative complication, I can be available. I have no such limitation after PITA, and therefore can schedule surgeries up to a few days prior to my vacation. I have yet to regret that change in policy. We have not had a postoperative bleed after IT, and the questions parents have had were easily handled by our staff. Finally, my overall satisfaction with practicing pediatric otolaryngology has improved so much, especially when many parents comment postoperatively, "This was really easy, just like you said it would be".

I hope this book will help you attain similar results, as well as improve the quality of life for many tonsillectomy patients.

Chapter 173

DIEP FLAP BREAST RECONSTRUCTION: TECHNICAL TIPS TO OPTIMIZE OUTCOMES AND AVOID COMPLICATIONS

Koichi Tomita* and Kenji Yano

Department of Plastic and Reconstructive Surgery,
Graduate School of Medicine,
Osaka University, Osaka, Japan

ABSTRACT

Progress in microsurgery techniques has popularized the use of the perforator flap, which enables minimal invasion into the donor site without sacrificing muscle. In breast reconstruction as well, one procedure that has become increasingly common is the transplantation of subcutaneous fat from the lower abdomen as a deep inferior epigastric perforator (DIEP) flap to the affected area. Recent developments in 3D imaging are also quite significant, allowing for 3D photography and 3D printing to be done even at the individual patient level. We have also come to rely more heavily on 3D imaging technology for breast reconstruction employing DIEP flaps, and have reported on its utility. In the present chapter, we focus on our experiences thus far, and present tips for safe maneuvering of DIEP flaps, as well as the implementation status of 3D imaging technology and its utility with regard to breast reconstruction using DIEP flaps.

Keywords: DIEP flap, breast reconstruction, 3-dimensional imaging, 3-dimensional printing

INTRODUCTION

In recent years, a dramatic increase in the number of breast cancer patients has led to a concomitant and daily increase in the needs and awareness surrounding breast reconstruction. Currently, breast reconstruction methods can be divided into the following three categories:

* Corresponding Author's Email: ktomita9@hotmail.co.jp.

1) transplantation of self tissue to the affected breast (following full or partial mastectomy); 2) use of a breast prosthesis (following full mastectomy); and 3) use of remaining breast tissue to ‘clean up’ the breast form (following partial mastectomy). Each method has its own set of pros and cons, and decisions concerning the application of any of these are made through conversations between the patient and physician as they consider patient preference, illness, and social background factors. The biggest advantage of breast reconstruction using self tissue such as subcutaneous abdominal fat is that it allows physicians to recreate soft breasts with a natural texture. However, for many years, this technique necessitated sacrificing muscle from the donor site. With the recent emergence of the concept of the perforator flap, this problem may have been resolved, at least from the standpoint of functional sacrifice [1].

Developments in 3D imaging technology have been substantial in recent years, and 3D photography and 3D printing have progressed to the point of being used at the individual level. Along with those developments, this technology is being applied in a variety of medical fields. Plastic surgery, where most surgeries are performed on the surface of the body, is one field that likely benefits from these developments substantially, and many attempts have been made to incorporate 3D imaging technology into treatments of various plastic surgery-related conditions [2, 3]. In recent years, we have become more heavily reliant on the use of 3D imaging technology for breast reconstruction using deep inferior epigastric perforator (DIEP) flaps [4, 5], and have reported on its utility [6]. In the present chapter, we focus on our experiences thus far, and provide tips on the safe maneuver of DIEP flaps. We also describe how we incorporate 3D imaging technology for DIEP flap breast reconstruction and report on the utility of this technology.

ANATOMY

Abdominal fat tissue is nourished by the superior epigastric vessels, the superficial and deep inferior epigastric vessels, and intercostal vessels. After branching off from the external iliac vessels, the deep inferior epigastric vessel (the feeding vessel of the DIEP flap) typically runs inward and upward, and from roughly 3-5 cm caudal of the arcuate line, courses cranially along the underside of the rectus abdominis muscle. Following this, many bifurcations occur in the vessels running through the muscle, yielding medial and lateral branches; notably, not all vessel types bifurcate. In addition, prior to bifurcating into medial/lateral branches, some will branch medially; this medial branch does not pass through the muscle, but directly enters the skin flap near the umbilicus (Figure 1). From blood vessels that pass through the muscles, several thick perforator branches thread through the anterior sheath of the rectus abdominis muscle to reach the adipose tissue, where they radiate out to nourish subcutaneous fat tissue. Most perforator branches are localized to the periphery of the umbilicus, and reportedly, an average of 6 perforator branches on each side with a diameter of 0.5 mm or larger, as well as 1-3 branches with diameters of 1 mm or larger, are found [7].

Figure 1. Variations in blood flow of the deep inferior epigastric vessels (all on the right side).

(A) Vessel types that can be divided into medial and lateral branches.

(B) Vessel type that does not make large bifurcations, but rather remains one vessel.

(C) Prior to bifurcating into medial/lateral branches, this type will branch medially. That branch does not pass through the muscle, but directly enters the skin flap (arrow).

PREOPERATIVE PREPARATION

1. Selection of Applicable Cases

The color Doppler method is used to confirm the presence of perforator branches of a certain diameter in the lower abdomen around the umbilicus [8]. If none are found, then either a free or pedicled rectus abdominis musculocutaneous flap is selected. In addition, the patient must have enough subcutaneous abdominal fat to repair the defective tissue. While we do not exclude outright any young women who wish to become pregnant in the future, we do feel they should avoid this procedure, if at all possible.

2. Preoperative Blood Vessel Evaluation and Selection of Perforator Branches

Of utmost importance is confirmation of the paths of the deep inferior epigastric vessels as well as the perforator branches. Previously, these were both evaluated only through color Doppler, but with the emergence of multidetector computed tomography (MDCT), all patients who can tolerate contrast agent now undergo a preoperative abdominal MDCT. This first evaluates the intramuscular route of the deep inferior epigastric vessels through 3D CT imaging, and then branch types mentioned above are categorized.

Perforator branches are then mapped, and those that could be included in the flap are selected in advance (Figure 2). Selection criteria involve, first and foremost, perforator branch thickness; as a rule, we select the thickest vessel (regardless of whether it is on the right or left side). If several vessels fulfill the selection criteria, we turn to other criteria such as the least intramuscular penetration (and thus greater ease of detachment), a strong network with the superficial inferior epigastric vessels, or a vessel on the side with no scars. If we are unsatisfied with the thickness of the perforator branch, we may consider including a total of 2 or 3 branches. However, in addition to the criteria mentioned above, those are selected in a combination that would minimize muscle sacrifice. In general, if perforator branches that originate from the medial and lateral branches are both included in the same flap, the muscular body between them must be cut, leading to more muscle damage. On the other hand, if perforator branches on the same side are selected, muscle damage is minimized, but the intercostal nerves that cut across between the branches must be cut and then rejoined. In addition, if too many perforator branches from the caudal end are included, the length of the vascular pedicle is shortened.

3. Preoperative Evaluation of Required Tissue Amount and Decisions Concerning the Use of Bipedicled DIEP Flaps

One disadvantage of using DIEP flaps is that the blood flow volume is lower than that of the rectus abdominis musculocutaneous flaps (RAMFs), which limits where it can be grafted [9]. Therefore, if a large amount of tissue is required for the transplant, a bipedicled DIEP flap should be considered [10]. At our institution, we simplify the surgical plan by pre-determining the necessary tissue volume as well as that of the flap that can be harvested using 3D imaging data and abdominal fat thickness, respectively [6].

Figure 2. 3D CT mapping of perforator branches. Measurements were taken to determine the distance from the umbilicus (landmark).

Figure 3. Use of 3D imaging for breast reconstruction using a DIEP flap (Reprinted from ref. 6).

To predetermine the necessary tissue volume, preoperative measurements of both breasts are first made using image analysis software (Breast Rugle®, Medic Engineering, Kyoto) (Figure 3A). For one-stage immediate reconstruction, the volume of the opposite (healthy) side is considered the necessary amount of tissue volume. For two-stage immediate reconstruction and delayed reconstruction, the difference in breast volume between the healthy and affected sides is considered the necessary tissue volume. Because we calculate both the volume of mammary gland tissue to be extracted and that of remaining breast skin tissue for one-stage immediate reconstruction, the necessary tissue volume may be slightly exaggerated in the evaluation. However, in our experience, the amount of error is not to the level that would affect the decision concerning whether a bipediced DIEP flap would be required or not, and perioperative correction is possible by measuring the excised tissue.

The measurement of extractable flap volume is somewhat affected by the flap extraction method, but we have found that this can be estimated by the following equation: (Total flap volume, ml) = (mean subcutaneous fat thickness (cm) after excluding the skin thickness at the center of the rectus abdominis) $\times$ (total flap area (cm²) as calculated by the imaging software) (Figure 3B). It also depends on the thickness, number, and location of the perforator branches, but if the estimate of necessary tissue volume exceeds 60-70% of the estimated total flap volume, then we plan for a bipediced DIEP flap (Figure 3C). However, if the numbers are borderline and difficult to determine, then perforator branches on both sides are preserved. After the flap is maneuvered epifascially, a perforator branch on one side is clipped, and perioperative determination is done with indocyanine green fluorescent imaging [11]. Even in these cases, a preoperative estimate of the percentage of the total required flap tissue is extremely useful for perioperative determination of whether or not an additional blood vessel is required.

TIPS ON MANEUVERING THE FLAP

In addition to the perforator branch that was selected through the MDCT perforator branch mapping, all viable perforator branches should be marked preoperatively on the abdominal skin using a color Doppler device and Doppler blood flow meter, as this makes perioperative identification of the targeted perforator branch relatively easy. With regard to flap design, the upper end of the umbilicus should represent the cranial margin for a transverse flap, and the caudal end should have a convex boat-shaped design. Below we describe how to maneuver a transverse flap.

First, the skin around the perimeter of the umbilicus is cut down to the fascia in the shape of a ring. After isolating the umbilicus, the skin for the entire flap is dissected. For the caudal end of the flap, the deep fascia is reached by going down perpendicularly. However, in that process, it is important to not damage the superficial inferior epigastric vessels. From these vessels, a thick vein is selected, followed to some extent to the proximal part, and then included in the flap. This can be used after flap transplantation if veins become problematic. For the cranial end of the flap, the superficial fascia is peeled back about 2-3 cm in the cranial direction, and this will lead to the deep fascia. By doing this, any mismatch in thickness between the cranial and caudal ends of the flap can be resolved when the harvested flaps are sewn together. It also enables the transplantation of more tissue than required.

Following this, the flap is peeled back and elevated laterally along the fascia. In this process, a more controlled peeling is possible with the use of a needle-shaped scalpel electrode. Once the lateral border of the anterior sheath of the rectus abdominis muscle is reached, careful peeling is done using dissecting scissors, and the perforator branches that were marked preoperatively are identified and preserved. An incision is made in the anterior sheath roughly 1 cm caudal and 3-5 mm lateral of the targeted perforator branch. From that point, the presence of the perforator branch underneath the anterior sheath is confirmed. In this way, initial confirmation of the presence of perforator branches farther under the anterior sheath makes it possible to avoid damaging perforator branches in cases where the perforator branch is attached as it runs along the anterior sheath.

Figure 4. Preoperative condition of patient who underwent mastectomy on the right side.

After dissecting the anterior sheath along muscle fibers and opening it up roughly 5 cm, the muscle is divided longitudinally along the muscle fibers in a retrograde fashion from the arterial flow, exposing the blood vessel that will form the pedicle. In thin muscle branches, it is best to stay as far from the vascular pedicle as possible while using bipolar cautery to carefully clot and dissect. Thicker branches should be handled with a microclip, as the peeling is performed until the blood vessel reaches the underside of the muscle body. Motor branches of the intercostal nerve that run transversely should be preserved as much as possible. If the intercostal nerve must be dissected because it is between perforator branches, postoperative muscular atrophy can be prevented by re-stitching the nerve following the flap harvest. When peeling back the blood vessels, it is important to envision this process as a “peeling the surrounding tissue away from the blood vessel, i.e., leaving only the blood vessel in place”, rather than tugging on the blood vessel to peel it away from the surrounding tissue. This will minimize any mechanical damage to the perforator branch. In cases for which the perforator branch is threaded through tendinous intersections, it is impossible to just isolate the perforator branch safely, so rather than trying to achieve the impossible, they are maneuvered along with the tendinous intersections.

After confirming separation of the blood vessel from the muscle body, a new 5-cm incision is made on the anterior sheath, from the lateral margin of the rectus abdominis in the caudal direction, and then the presence of the deep inferior epigastric vessels that insert into the underside of the muscle body from the lateral side of the muscle body is confirmed. This is then peeled back in the cranial direction and connected with the blood vessel that was peeled back earlier. During this process, it is very important to avoid damaging the thick intercostal nerve running transversely from the lateral side. The peeling is also conducted in the caudal direction until the bifurcation of the external iliac vessels is reached.

After the entire flap is peeled back to the fascia, the region of transplantable flap with stable blood flow is determined through subjective evaluation such as flap color or blood color, as well as objective evaluations such as perioperative ICG fluorescent angiography [11]. Any regions with insufficient blood flow are excised.

BREAST MOUND FORMATION BY CREATING A BREAST MOLD THROUGH 3D PRINTING

Using the aforementioned imaging software, it is possible to create a mold image of the breast on the opposite side, using 3D data obtained preoperatively. After this, the data that are transformed to a mirror image can be printed on a 3D printer. This enables the creation of a breast mold on the affected side, which can be gas sterilized and used perioperatively (Figure 3D). Following anastomosis/de-epithelialization of the flap, it is inserted into the mold, with careful attention being paid to the vascular pedicle (for one-stage immediate reconstruction accompanying nipple/areola resection, a part of the de-epithelialization is done later). First, after determining the most appropriate flap placement that will avoid placing tension on the vascular pedicle, any part of the flap that does not fit in the mold is resected (Figure 3E). In the event that the cranial side of the flap is thicker, adipose tissue from under the superficial fascia is removed and adjustments are made. When adjusting the amount of flap, one must remember that the chest wall protrudes out slightly in the front, rather than being flat. Using a

measuring spoon as an analogy, the whole spoon leveled off would be excessive; it is important to have not quite a full measuring spoon. In addition, as the breast molds are created according to the form of the body surface, the volume of breast skin is not taken into consideration. As a result, immediately after surgery, the reconstructed breast is slightly bigger than that on the healthy side, but as the flap tends to shrink postoperatively by about 5-10% [12], we feel that this works out quite nicely. In patients with high breast projection, breast mound construction is performed using several absorbable sutures to stabilize the flap on the caudal side. This work can be done prior to the anastomosis, but we opt to perform these procedures afterwards, primarily because it allows for some time to observe the condition of the anastomosis, and because it enables easier de-epithelialization of the flap.

POSTOPERATIVE MAINTENANCE

For 24 hours after surgery, a Doppler blood flow meter and the Doppler method should be used to monitor the flap blood flow every 4 hours. For 1 week after that, blood flow should be checked roughly three times a day. The patient should become ambulatory the day after surgery, and activity levels should be increased gradually thereafter. The abdominal suction drain should be removed between postoperative day 7 and 10, after which the patient can be discharged.

REPRESENTATIVE CASE

A 42-year-old female underwent mastectomy and sentinel node biopsy at another institution for cancer in her right breast, and was referred to our institution for delayed reconstruction (Figure 4). First, we inserted a subcutaneous tissue expander and performed mastopexy of the opposite breast, followed by reconstruction using a DIEP flap 4 months later. While the preoperative 3D analysis estimated that roughly 525 ml of tissue would be required, the total estimated flap volume was roughly 810 ml (roughly 65%). As such, we planned for a bipedicle DIEP flap that included one perforator branch from the right side medial row as well as 2 perforator branches from the left side medial and lateral rows (Figure 5A). Following mastopexy of the healthy side, a breast mold was created based on 3D data obtained after the breast form had stabilized. The lateral branch of the deep inferior epigastric vessels on the right side was anastomosed to the main trunk of the deep inferior epigastric vessels on the left (Figure 5B), and the right deep inferior epigastric vessels were anastomosed to the internal mammary vessels. After de-epithelialization, the flap was inserted into the breast mold, and excess flap tissue was excised (of the total 805 g of flap tissue, 560 g transplanted) and the breast mound constructed (Figure 5C). After inserting the flap into the subcutaneous pocket in the anterior chest, an inframammary fold was created using Nava's technique [13] (Figure 5D). Postoperatively, the flap showed complete engraftment, and the patient had a soft and symmetrical breast (Figure 6).

Figure 5. Perioperative findings. (A) Following subcutaneous insertion and expansion of the tissue expander, and then mastopexy of the other breast, we planned a bipedicle DIEP flap that included one perforator branch on the right side medial row and two perforator branches from the left side medial and lateral rows. (B) Anastomosis of the lateral branch of the right deep inferior epigastric vessel and the main trunk of the left deep inferior epigastric vessel. (C) The flap was inserted into the breast mold. Excess flap tissue was excised and the breast mound was formed. (D) After inserting the flap into the anterior chest subcutaneous pocket, we used Nava's technique to create an inframammary fold.

Figure 6. Postoperative status at 10 months. A sufficient amount of tissue was transplanted, allowing for reconstruction of a soft and symmetrical breast.

CONCLUSION

We have documented some of our recent experiences and innovations with breast reconstruction using DIEP flaps. From the perspective that DIEP flaps minimize muscle sacrifice, allowing for transplant of tissue with a relatively large volume and area, we feel that

this technique is an extremely useful option for breast reconstruction. In addition, with recent progress in vascular anatomy studies, as well as the prevalence of MDCT and 3D imaging technologies, increasingly safe and accurate preoperative plans and simulations are now possible. We anticipate even more developments in this standard procedure that uses self tissue for breast reconstruction following mastectomy.

BIOGRAPHICAL SKETCH**Koichi Tomita****Affiliation:**

Department of Plastic and Reconstructive Surgery
Graduate School of Medicine, Osaka University

Education:

Osaka University, Medical School M.D., 2000
Osaka University, Graduate School of Medicine Ph.D., 2007

Business Address:

2-2 C11 Yamadaoka Suita, 5650871 Osaka, Japan

Research and Professional Experience:

Dr. Tomita's research has concentrated in the area of reconstructive microsurgery, including breast reconstruction, facial nerve reconstruction, and head and neck reconstruction. Clinical research areas of interest include breast reconstruction using 3-dimensional imaging and facial nerve reconstruction using multiple motor sources. Basic research areas of interests includes improvement of peripheral nerve regeneration using adipose-derived stem cells and in vivo molding of soft tissue using an absorbable mold.

Professional Appointments:

Since 2007 Assistant Professor, Osaka University
2009-2011 Research fellow, Blond McIndoe Research Laboratories, University of Manchester

Honors:

2009-2011 Uehara memorial foundation research fellowship
2013, 2014 President's incentive award, Osaka University

Chapter 174

EFFECT OF RADIOTHERAPY ON IMPLANT-BASED IMMEDIATE BREAST RECONSTRUCTION WITH OR WITHOUT ACELLULAR COLLAGEN MATRIX: POTENTIAL STRATEGIES TO IMPROVE OUTCOME

Baek Kim* and Rajgopal Achuthan

Department of Breast Surgery, St. James's University Hospital, Leeds, UK

ABSTRACT

Implant-based immediate breast reconstruction has evolved rapidly over the past decade. The emergence of human, porcine, and bovine acellular collagen matrices (ACM) has had significant impact resulting in a marked rise in implant-based immediate reconstructions. The matrices are used to provide improved lower pole coverage of the reconstructed breast enabling a one-stage reconstruction with a fixed volume implant or an expander in cases where a larger volume reconstruction is required. This is in contrast to the technique of complete submuscular tissue expander reconstruction, which was associated with limited implant or expander volume as well as restricted lower pole projection. Understandably, implant-based immediate breast reconstruction with ACM is therefore increasingly utilised in oncological and risk reducing settings.

Post-mastectomy radiotherapy remains a key adjuvant treatment modality as it improves locoregional control as well as overall survival in breast cancer patients. However, its use in patients who have undergone implant-based reconstruction can be detrimental with potential for complications such as infection, mastectomy flap necrosis, capsular contracture, and explantation necessitating revisional surgery. Therefore, managing this group of patients requires careful multidisciplinary approach and planning. The main purpose of this review article is to examine the effect of post-mastectomy radiotherapy on the outcome of implant-based immediate breast reconstruction with or without acellular collagen matrix. We will additionally examine the literature to determine if there is any potential protective benefit of ACM usage in patients who receive post-mastectomy radiotherapy. The review will also attempt to identify potential strategies that can be utilised to improve outcome in these patients. The strategies will

focus on patient and surgical risk factors, alternative reconstructive options including autologous reconstruction, as well as adjunctive surgical techniques to improve patient outcome.

Keywords: breast reconstruction, radiotherapy, mastectomy, implant, acellular dermal matrix, acellular collagen matrix

INTRODUCTION

Immediate breast reconstruction (IBR) has been shown to be oncologically safe [1, 2], cost-effective [3], and importantly reduce psychological morbidity [4]. Expander/implant-based breast reconstruction accounts for 65% of all breast reconstruction in the United States [5]. Acellular collagen matrix (ACM), otherwise commonly known as acellular dermal matrix, is being used increasingly [6] in expander/implant-based IBR. ACM provides improved lower pole coverage of the reconstructed breast enabling a one-stage reconstruction with a fixed volume implant or an expander in cases where a larger volume reconstruction is required. ACM improves the aesthetic outcome of expander/implant-based IBR. This is in contrast to the traditional complete submuscular tissue expander reconstruction with disadvantages of limited implant/expander volume, the need for multiple visits for expansion, as well as limited lower pole projection.

Post-mastectomy radiotherapy (PMRT) remains a key adjuvant treatment modality where indicated, and has been shown to improve locoregional control as well as overall survival [7]. The oncological benefit of PMRT is recognized but it is associated with potential side effects including tissue fibrosis, reduction in dermal blood flow, and tissue hypoxia. As a result patients, particularly with implant-based reconstructions, can suffer from complications such as infection, mastectomy flap necrosis, capsular contracture, and explantation. Our aim is to examine the effect of PMRT on the outcome of expander/implant-based IBR with or without the use of ACM. We will attempt to identify strategies that can be utilised to improve outcomes in these patients. The strategies will focus on patient and surgical risk factors, alternative reconstructive options, as well as adjunctive surgical modalities to improve patient outcome.

THE EMERGENCE OF ACELLULAR COLLAGEN MATRIX

Traditional two-stage reconstruction involves submuscular expander insertion at the time of skin-sparing mastectomy. Raising the pectoralis major muscle fibers and the fibers of serratus anterior muscle laterally provides lower pole coverage of the expander. Expansion with saline is performed gradually to achieve the desired reconstructed breast volume. A subsequent operation is performed where the expander is exchanged for a permanent implant. However, it is difficult to create a natural ptotic breast, and the initial implant or expander volumes are limited by the anatomical boundaries.

ACM allows better lower pole coverage of the reconstructed breast, and hence a more natural aesthetic reconstruction. It is sutured on to the lower edge of the pectoralis major muscle and to the inframammary fold. It acts as a mechanical support, and allows more precise positioning of the expander or implant. Greater intraoperative filling volume is

possible using ACM [5]. This in turn enables one-stage IBR, which has the potential to be cost-effective [8]. Human ACM, more commonly utilised in the United States, include AlloDerm, Neoform, DermaMatrix, and FlexHD [9]. They are created by treating human cadaveric skin to remove all cellular and immunogenic components. This leaves a basement membrane and cellular matrix that provides a scaffold. In Europe, human tissue products are not used widely due to regulatory restrictions and hence Porcine (e.g., Strattice) and bovine ACM (e.g., Surgimend and Veritas) are utilised instead [10-12] (Figure 1).

Figure 1. Post-operative images of a patient who underwent implant-based immediate breast reconstruction with ACM on the right with contralateral left breast reduction for symmetry.

CRITERIA FOR ADMINISTRATION OF POST-MASTECTOMY RADIOTHERAPY

Post-mastectomy radiotherapy (PMRT) is beneficial in patients particularly those where the risk of loco-regional recurrence is greater than 20% [13]. Tumour size and nodal status are key factors in determining which patients are offered PMRT. Typically in patients with T3 or T4 disease and those with four or more positive axillary lymph nodes PMRT is indicated [13]. Other important factors in decision to offer PMRT include tumour grade, presence of lymphovascular invasion, age less than 40 years, close margins of less than 1mm, and the presence of significant extracapsular nodal spread [13].

The degree of nodal involvement is important in the decision making to offer PMRT. A meta-analysis of Early Breast Cancer Trialists Collaborative Group (EBCTCG) showed that for patients with four or more positive axillary nodes, PMRT reduced overall recurrence (RR 0.79) and breast cancer mortality (RR 0.87). For patients with negative axillary nodes, PMRT did not confer benefit with regards to recurrence and survival rates. In the patients with one to

three positive axillary nodes, PMRT resulted in recurrence and survival benefits even in the presence of other systemic therapies [14]. However, the question remains as to whether all patients with one to three positive axillary lymph nodes would benefit from PMRT given their relatively lower risk of recurrence. Yao et al. examined the United States National Cancer Data Base, and stated that PMRT is being increasingly utilised in patients with one to three positive axillary lymph nodes; the proportion of patients receiving PMRT in this subgroup increased from 23.9% in 2003 to 36.4% in 2011 [15]. The SUPREMO [Selective Use of Postoperative Radiotherapy After Mastectomy] trial investigates outcome in such patients who have less than four positive axillary lymph nodes and the results of the trial is awaited [16]. A population-based study by the Swedish Western and Southeastern group found that omission of PMRT in patients with one to three positive axillary nodes did not influence survival [17].

Tumour size is another predictor of risk with PMRT improving outcomes in patients with large tumours. Historically, patients with T3 and T4 tumours have been offered PMRT [18]. However, Taghian et al. report that patients with T3N0 tumours treated by mastectomy should not routinely receive PMRT due to the low rate of loco-regional failure [19].

A subset of patients with T1 and T2 tumours with one to three positive nodes may be offered radiotherapy. A recent meta-analysis by Li et al. supports the use of PMRT in this group of patients due to achievement of significant reduction in loco-regional recurrence [20]. A retrospective study from the British Columbia Cancer Agency showed that the risk of loco-regional recurrence at 10 years was 12.7% for T1 or T2 tumours with one to three positive axillary lymph nodes. This study showed that age <45 years, >25% positive lymph nodes, medial tumours, and negative oestrogen receptor status independently increased the risk of loco-regional recurrence [21]. This is corroborated by a study by Jwa et al. who concluded that PMRT may be beneficial for patients with non-luminal breast cancer with one to three positive axillary lymph nodes [22]. A further study by Truong et al. concluded that nodal ratio (positive/excised nodes) of greater than 0.2 was associated with locoregional recurrence rate of >20%, and hence these patients may benefit from PMRT [23]. Study by Trovo et al. also identified pre-menopausal status, oestrogen receptor negative cancer, grade 3 tumours, and the presence of lymphovascular invasions as potential risk factors for loco-regional failure after mastectomy and should therefore prompt consideration for PMRT [24].

Therefore, selection of patients for PMRT requires a careful multidisciplinary approach to optimise oncological outcome in patients, and the above potential predictive factors should be taken into account when deciding which patients should be offered PMRT.

THE EFFECT OF POST-MASTECTOMY RADIOTHERAPY ON IMPLANT-BASED IMMEDIATE BREAST RECONSTRUCTION WITHOUT ACM

A Dutch study [25] reported in 2000 showed that complication rates following IBR with submuscular expanders was 27% in the PMRT group compared to 13% in those without PMRT (median follow-up 30 months). Christante et al. [26] report an explantation rate of 31% in patients who underwent PMRT after immediate expander reconstructions, in contrast to 6% in those who did not receive PMRT.

Another study by Reefy et al. [27] showed that capsular contracture rate was 85% in patients who required PMRT or had previous radiotherapy as opposed to 13% who did not receive radiotherapy. A study [28] from Memorial Sloan-Kettering Cancer center showed that at median follow-up of 86 months, the rate of permanent implant removal or replacement was 29% at 7 years post-radiotherapy. Cordeiro et al. performed a comparison analysis of non-irradiated implanted based reconstruction versus implant-based reconstruction followed by PMRT. With mean follow up time of 56.8 months, implant loss rate was 0.5% in the former as opposed to 9.1% in the latter. Grade III to IV capsular contracture rate was 11.1% and 27.6% respectively. Aesthetic results, as assessed by surgeons, were inferior in patients who received PMRT [29]. A meta-analysis by Barry et al. [30] showed that radiotherapy exposure after implant-based IBR was associated with a 4.2 fold increase (95% CI, 2.4-7.2) in post-operative complications compared to no radiotherapy.

THE EFFECT OF POST-MASTECTOMY RADIOTHERAPY ON IMPLANT-BASED IMMEDIATE BREAST RECONSTRUCTION WITH ACM

In a study by Colwell et al. [31] where ACM was used, complication rates increased to 25.2% in patients who underwent radiotherapy compared to 13.9% without radiotherapy ($p = 0.005$). Similarly, Clemens et al. [32] from M.D. Anderson reported a complication rate of 43.3% in patients who received radiotherapy compared to 15.6% in those without radiotherapy, where both groups underwent reconstruction using ACM. In particular, mastectomy flap necrosis was seen in 26.7% in the radiotherapy group versus 7.5% in the non-radiotherapy group. Rawlani et al. [9] reported outcomes in ACM-based reconstruction patients receiving radiotherapy ($n = 26$) versus the no radiotherapy ($n = 95$). Complication rate was 30.8% in the former group versus 13.7% in the latter group; mastectomy flap necrosis and implant exposure were both high at 15.4% in the radiotherapy group versus 4.2% in the non-radiotherapy group. In a study by Salzberg et al. [33] evaluating the use of one-stage implant-based IBR with ACM, radiotherapy was received by 4.5% of patients where the complication rate was 14.3% versus 3.9% in the non-radiotherapy group. These studies show that radiotherapy seems to be detrimental in patients who undergo implant-based reconstruction using ACM (Figure 2).

Figure 2. Complication following implant-based immediate breast reconstruction with acellular collagen matrix.

COMPARISON OF OUTCOME IN IMPLANT-BASED IMMEDIATE BREAST RECONSTRUCTION WITH OR WITHOUT ACM (IN GROUPS NOT REQUIRING ADJUVANT PMRT)

A Meta-Analysis from Kim et al. [5] reviewed 48 relevant studies comparing complication rates in patients with with human ACM versus submuscular implant/expander reconstruction. AlloDerm was used in the majority of studies. Total complication rate of 15.4% was noted in the ACM group (n = 2037) as opposed to 14% in the submuscular group (n = 12,847). There was a small increase in infection (5.3% vs. 4.7%), flap necrosis (6.9% vs. 4.9%), and seroma rates (4.8% vs. 3.5%) in the ACM group compared to the submuscular group. However, the rates of reconstructive failure were similar at 3.8% in both the ADM and in the submuscular group. ACM is tested to confirm the absence of microbial contamination, but is not sterile [34]. This may account for the higher infection rate in the ACM group. The higher flap necrosis rate may be explained by greater intraoperative filling volume in the ACM group (mean = 264.9ml) versus the submuscular group (mean = 187.1ml). The minor increase in the overall complication rates may be explained by the learning curve of a new surgical technique. This suggestion is corroborated by study from Colwell et al. [31]; complication rate was 21.4% in the surgeons' first year of performing the procedure, but 10.9% in the subsequent years. Studies with longer follow-ups are required, as the mean follow-up time was 13.8 months in the ACM group, compared to 28.3 months in the submuscular group.

IMPACT OF RADIOTHERAPY ON IMPLANT-BASED IMMEDIATE BREAST RECONSTRUCTION WITH OR WITHOUT ACM

There are comparatively few studies which directly compare the effect of radiotherapy on implant-based IBR with or without ACM. A study by Seth et al. [35] compares the effect of PMRT in the ACM group versus the non-ACM group. They found no significant increase in complication rate with PMRT in the ACM group (n = 74), but significant increase in complication rate was observed in the non-ACM group (n = 49). However, in a study by Parks et al. [36], which compared ACM (n = 27) versus non-ACM (n = 37) reconstruction, radiation significantly increased the rate of expander loss only in the ACM group. It is worth noting that the evidence for the effect of radiotherapy on ACM versus non-ACM implant reconstructions is based on Level III studies. Additionally, the number of patients included for analysis is small. No definitive conclusion can be drawn at present regarding whether ACM has any protective effects against the detrimental effect against radiation. Further level I direct comparison studies with longer-term follow-up are required.

STRATEGIES TO REDUCE COMPLICATION RATES IN PATIENTS WHO REQUIRE POST-MASTECTOMY RADIOTHERAPY

Predicting which patients require PMRT may enable better pre-operative planning and reduce complication rates. Christante et al. [26] reported that T2 tumours, positive axillary

lymph node status, and the number of positive sentinel lymph nodes were independent predictors of PMRT. Therefore, performing upfront sentinel node biopsy prior to reconstruction may provide useful information to assess the likelihood of PMRT. Mannu et al. compared complication rates prior to and after introduction of upfront sentinel node biopsy for patients undergoing mastectomy and IBR. They reported significant reduction in complication rates after introduction of upfront sentinel node biopsy. This was attributed to the fact that prior to the usage of upfront sentinel node biopsy, the proportion of patients receiving unexpected radiotherapy after implant-based reconstructions was higher [37]. Upfront sentinel node biopsy helped identify these patients allowing better planning and avoiding implant-based approaches.

Delayed reconstruction can be an alternate approach in patients who are at high likelihood of receiving PMRT, and indeed Michigan Breast Reconstruction Outcome study showed that immediate reconstruction confers two-fold increased odds for complications compared to delayed reconstruction [38]. This finding is supported by Sullivan et al. who reported higher complication rate and capsular contractures in immediate tissue expander reconstruction compared to delayed expander reconstruction [39]. A survey of breast surgeons in the United Kingdom and United states showed that when PMRT was planned, the surgeon's preference was for delayed or delayed-immediate breast reconstruction [40, 41]. However, this is counter-balanced against the desire of the patient who may wish to pursue an immediate type of reconstruction. Delayed reconstruction more frequently results in the need for recruitment of autologous tissue with associated donor site morbidities. Furthermore, delayed reconstruction using expander/implant solely is likely to result in inferior aesthetic outcome due to loss of the skin envelope following a mastectomy. Importantly this latter technique is not advised in patients who have received PMRT.

Another approach when PMRT is expected is to consider the delayed-immediate breast reconstruction [42]. In this approach skin-sparing mastectomy is performed with a submuscular expander/implant with an ACM, enabling skin-preservation. The use of an ACM in this setting allows for achievement of the desired volume circumventing the need for multiple expansions, which can potentially delay PMRT. Rozen et al. recommends full expansion of the expander prior to radiotherapy with an aim of maximising the amount of regional tissue available for future reconstructive procedure [43]. Once radiotherapy is complete, the definitive delayed reconstruction can be performed.

Nava et al. compared outcome in three groups [44]; patients receiving PMRT on permanent implant versus tissue expander, and patients who did not require radiotherapy. Reconstructive failure rate was 40% in the tissue expander group, compared to 6.4% in the permanent implant group, and 2.3% in the control group. However, the underlying pathophysiology as to why permanent implants tolerate radiotherapy better than expanders in this study remains unclear.

There is evidence to support the use of polyurethane implants in patients who are likely to need or have already received PMRT [45]. Ideally following radiotherapy, in the setting of an implant/expander reconstruction, one considers revisional surgery for complications such as capsular contracture by transfer of autologous tissue from another site. In patients where this is not feasible or who have strong desire to avoid donor site morbidity, the use of polyurethane implants can be considered. The timing of exchange or revision of expander to permanent implant after PMRT can impact outcome. A study by Peled et al. [46] showed that delaying the expander-implant exchange to greater than 6 months after radiotherapy resulted

in a significant reduction in post-operative complication rates compared to less than 6 months (7.7% versus 22.4%; $p = 0.036$).

An alternative approach may be to pursue autologous IBR, but some patients may not have sufficient tissue for fully autologous reconstruction, and evidences suggest that radiotherapy has detrimental effects [30] on autologous reconstructions such as fat necrosis, which may be a complication of less significance as compared to loss of an implant reconstruction. An online risk calculator tool such as the Breast Reconstruction Risk Assessment Score (<http://www.BRAScore.org>) may aid in perception of risks for different types of breast reconstruction for the patients and clinicians involved. This assessment tool takes account of radiotherapy status [47]. Other surgical approaches have been reported as alternatives to ACM. One such technique is the autologous dermal sling-based IBR [48]. The inferior dermal sling consists of a de-epithelised skin flap created from the lower pole of the breast when using a Wise pattern approach. This provides lower pole support in a similar fashion to ACM. This approach is suitable only in patients with an appropriate degree of ptosis where skin-reducing mastectomies are considered. Another technique is the use of dermal autografts. Lynch et al [49] performed wide excision of the pre-existing abdominal scars to provide the lower pole coverage instead of ACM. The techniques of inferior dermal sling and dermal autografts are cost effective, but further research is required to determine outcomes in the setting of radiotherapy.

Further considerations include the site of skin sparing mastectomy incision with the inframammary incision reported to have a higher rate of wound breakdown and implant loss following radiotherapy. The authors attribute this to the inframammary position having a higher rate of moist desquamation due to its dependent position. Furthermore, tissue coverage at the inframammary position is less compared to peri-areolar based incision [50].

Ribuffo et al. describe protective effects of lipofilling after expander based IBR and PMRT. This is followed by exchange of the expander to an implant after at least 3 months from the completion of fat grafting. They have reported encouraging early results with reduced explantation rates in patients who were treated in this manner [51]. Serra-Renom et al. similarly utilise fat grafting after PMRT in patients who received expander implant breast reconstruction. They reported low capsular contracture rates at follow up time of 12 months [52]. Furthermore, Panettiére et al. reported lipofilling in 61 consecutive patients who underwent implant-based breast reconstruction followed by PMRT. Improvements in aesthetic outcome, explantation rates, and capsular contracture rates were reported in those treated with lipofilling [53].

It is important to examine general surgical and patient risk factors specific to implant-based IBR. A meticulous surgical approach and addressing modifiable potential risk factors is likely to minimise risk of complications in this potentially high risk patient group who may additionally require PMRT. A published guideline from the Association of Breast Surgery and the British Association of Plastic, Reconstructive, and Aesthetic Surgeons advise a cautious approach in patients undergoing an implant-based ADM IBR with body mass index >30 , simultaneous axillary lymph node dissection, PMRT, smoking, and mastectomy weight >600 gram [54]. Surgical site infection in patients with implant-based IBR may lead to subsequent implant loss. Barr et al. have produced a peri-operative 'theatre implant checklist' for surgical site infection prevention in implant-based breast surgery. This checklist is based on current review of literature and considers important aspects such as peri-operative

antibiotics usage, alcohol-based skin preparation, laminar air flow, minimal theatre traffic, irrigation of implant pocket, double gloving, and conductive warming [55].

Another strategy may be to consider neoadjuvant chemotherapy (NACT). In general, patients who are likely require PMRT have larger tumours with axillary nodal metastases. These patients would also be obligate candidates for chemotherapy. Historically, these patients would have undergone mastectomy, adjuvant chemotherapy, followed by PMRT. Instead, these patients could potentially undergo NACT, followed by mastectomy depending upon tumour response to NACT. Analysis of the NSABP B-18 and B-27 NACT trials showed low rate of loco-regional failure in patients who achieve complete pathological response (cPR). Potentially those patients achieving cPR post-NACT who then requiring a mastectomy could potentially be spared PMRT. The NSABP B-51 trial is currently recruiting patients with an aim of answering this question [56].

DISCUSSION

This review highlights the detrimental effect of radiotherapy on implant-based IBR with or without ACM. Currently there is lack of evidence to show that ACM has any protective effect against radiotherapy. However, the use of ACM is advocated in general, especially when the likelihood of PMRT is low. It is worth noting that most studies were centre or surgeon-specific. Few multicentre studies have been published; a Danish study examined outcome from 9 different centres [57], and the Michigan Breast Reconstruction Outcome Study project involved 23 surgeons from 12 institutions [38]. In the future, more multicentre studies with longer-term follow-ups are required. Currently in the United Kingdom, the National Implant Breast Reconstruction Audit (iBRA) is collecting data on all type of implant reconstruction performed with over 1700 patients recruited (<http://www.ibrastudy.com>).

Potential strategies to improve patient outcome in implant based breast reconstruction
Consider risk factors to help select appropriate patients • As outlined in the ABS and BAPRAS guideline for ADM assisted breast reconstruction • The Breast Reconstruction Risk Assessment score (http://www.BRAScore.org)
Anticipate need for PMRT based on pre-operative tumour characteristics (utilise upfront sentinel lymph node biopsy)
If PMRT anticipated, consider -ACM implant/expander reconstruction; also consider polyurethane implant -Autologous immediate reconstruction -Delayed-immediate reconstruction with skin envelope preservation -Delayed reconstruction -Neoadjuvant chemotherapy
Minimise potential risks during surgery -'Theatre implant checklist' -Scar placement for skin sparing mastectomy
Consider adjunctive procedure post-radiotherapy -Lipofilling procedure -If revisional surgery is required, ideally tissue transfer is indicated -In patients who decline tissue transfer, consider revisional surgery with polyurethane implant

Figure 3. Potential strategies to improve patient outcome in immediate implant-based reconstruction in setting of post-mastectomy radiotherapy.

The aesthetic outcome in implant-based IBR deteriorates with time, particularly without ACM use [58]. Studies show that IBR with ACM results in superior aesthetic outcome and reduced rates of capsular contracture, compared to IBR without ACM [59].

With development of surgical technology, ACM has resulted in improvement of implant-based IBR aesthetically and in terms of enabling direct to implant one-stage IBR with its associated advantages. However, similar problems are faced with regards to PMRT and its associated detrimental effects. This chapter has highlighted potential strategies currently described in the literature in order to improve patient outcome (Figure 3).

Chapter 175

PATIENT SATISFACTION FOLLOWING AUTOLOGOUS OR HETEROLOGOUS BREAST RECONSTRUCTION

Laura Sita-Alb*, Laura Duta and Lucian Fodor

Plastic and Reconstructive Surgery Unit, Emergency County Hospital,
Cluj Napoca, Romania

ABSTRACT

The "Health" cannot be anymore defined just from a physiological point of view, a good self-esteem, sexuality and quality of life are essential for a healthy patient. Today medicine is more and more direct towards the patient, giving them more choices, control and information. To be able to accurately measure health care outcomes, patient satisfaction data cannot be disregarded.

Every year more than 60.000 American patients are subjected to a mastectomy, a surgery that is highly mutilating especially for young women, and from this 20-40% will undergo a breast reconstruction. In front of a large variety of solutions the patient should be aware of her opportunities. Whether or not a candidate for an autologous, prosthetic or autologous and prosthetic breast reconstruction the patients should know what to expect.

What is, indeed, the best technique, an autologous or a heterologous reconstruction? And if is an autologous, which one gives the best results: the abdominal flaps (pedicled or perforator) the latissimus dorsi flap, the gluteal flaps or a combination of flaps with prosthetic reconstruction? In the past years a large number of studies assessing patient satisfaction and quality of life were published, comparing different techniques (autologous versus autologous, autologous versus heterologous, heterologous versus heterologous) in their attempt to improve patient health-care.

Lately there is a unanimous finding that shows that patients are mostly satisfied, and have a higher long-term satisfaction following an abdominal autologous breast reconstruction, when compared to any other reconstruction techniques.

Keywords: patient satisfaction, breast reconstruction, autologous breast reconstruction, prosthesis breast reconstruction, DIEP flap, abdominal flaps

INTRODUCTION

The concept of health, in modern times, cannot just be defined as freedom from pain or physical disease. It involves the overall condition of being sound in body and mind, completed by psychosocial well-being and sexual well-being. A healthy and satisfied patient, as a member of society, sets the grounds for a healthy and happy society. Ergo, modern medicine tends to focus on the patient as an individual, giving the patient a voice with regard to treatment decisions by providing multiple options, the necessary knowledge, information and medical data, including other patients' reported outcomes. In order to accurately measure health care outcomes, patient satisfaction data cannot be disregarded.

Over 296,000 American women were diagnosed with breast cancer in 2013 [1], ranking breast cancer in 1st place in non-skin cancer neoplasms in the American female population [2]. Although early stage diagnosed patients are presented with the choice of conservative treatment, more than 25% undergo mastectomy [3, 4]. This is a mutilating process, harming female femininity, affecting not only the patient's life but their partners and families as well, and is connected to numerous psychosocial disorders [5-10]. Less than 40% of thus traumatized patients will proceed to a breast reconstruction, viewed by many as a way to restore one's self-image, and the final step in breast cancer treatment. Faced with a world of solutions, the patient should be aware of the multiple options available. This is where the doctor's experience and knowledge, along with other patient's experience and reported outcomes, should guide the patient in finding the best solution for herself.

WHAT DO PATIENTS EXPECT ONCE DECIDING PRO RECONSTRUCTION?

The most frequent motive pro reconstruction is a return to normalcy and a feeling of wholeness that a restored breast can generate for its recipients, along with the psychosocial benefits resulting from increased self-esteem and better performance in social circles [11]. For most women, breast reconstruction represents the final step in cancer treatment and healing [11]. That being said, most women do not know what to expect in the aftermath of reconstruction and proceed towards surgery with different expectations than the final outcome. For example, most patients are anxious for nipple reconstruction, unaware of the lack of sensation afterwards, or expect perfect symmetry post-unilateral prosthesis reconstruction [11]. Unfulfilled or unrealistic expectations represent a major source of post-reconstruction dissatisfaction, underlining once more the importance of patient education beforehand. In order to avoid such discomfort, both surgeon and patient should move forward from starting on common ground.

HOW CAN WE QUANTIFY THE IMPACT OF BREAST RECONSTRUCTION ON A PATIENT'S QUALITY OF LIFE?

Moving forward, the quality of a surgeon's work should be validated by the positive impact it has on a patient's life. Due to the great pallet of options, how does the surgeon

decide the best fit for each case? Most times, the emotional cancer patient can be overwhelmed with information and technical aspects of reconstruction possibilities. Relying on the premise that the surgeon knows best, the patient may end up with unsatisfactory results due to making the wrong decision. As a solution, patients' reported outcomes came to the scene, thereby providing data to create a bridge between surgical knowledge and patient expectations.

Table 1. Breast-Q reconstruction module [13]

Quality of Life	Satisfaction with	Expectations for
PSYCHOSOCIAL WELL-BEING - body image - self-esteem - confidence - emotional integrity	BREASTS - breast appearance - clothing - bra fit - rippling (implant related)	STAFF PROVIDED SUPPORT - care - emotional support
SEXUAL WELFARE/BODY IMAGE - sexual confidence - sexual attractiveness (with/without clothes) - lack of self-consciousness during intercourse	NIPPLES (NAC) - shape - color - natural aspect - projection	PAIN during 1st week post-reconstruction
PHYSICAL WELL-BEING CHEST/UPPER BODY - pain - breast area related distress - activity limitation - discomfort-induced sleep problems ABDOMEN/TRUNK (TRAM/DIEP flaps) - abdominal weakness leading to activity impairment - negative physical consequences BACK/SHOULDER (LD flap) - negative physical consequences - arm and shoulder activity impairment	ABDOMEN - appearance - scars - navel position BACK - scar appearance - scar location OUTCOME - overall assessment - met expectations (esthetic appearance) - impact upon life - decision toward surgery CARE - information - medical staff - surgeon - office staff	RECOVERY - during 1st week post-reconstruction COPING - during 1st year post-reconstruction BREAST APPEARANCE 1 year post-reconstruction PSYCHOSOCIAL WELL-BEING 1 year post-reconstruction

Starting in 2012, BREAST-Q (Table 1) has been largely embraced by the medical community as a means to quantify and convey patient reported data regarding breast surgery. It is a computer software program developed by Pusic et al. [12], designed to analyse a women's perspective concerning breast surgery by evaluating and quantifying different parameters associated with satisfaction post-breast surgery. The parameters included in the reconstruction module can be reviewed in Table 1 [13].

Other means for analyzing outcomes have been developed, from a panel of specialists evaluating photographs and measuring a set of established parameters [14], to computer

program aesthetic assessment of reconstructive results (BCCT.core)[15], all in the attempt to make the best decision for each patient.

TIMING OF RECONSTRUCTION: NO RECONSTRUCTION, IMMEDIATE OR DELAYED RECONSTRUCTION

Reasons for Breast Reconstruction Refusal

The vast majority of patients (60-80%) [16] choose not to undergo breast restoration surgery after mastectomy. The most cited reason for reconstruction refusal is to avoid additional surgery, while other common reasons include low level of education, older patients or patients presenting comorbidities, fear of a reconstructed breast shielding cancer recurrence [17, 18], financial aspects, or the need for chemotherapy [19]. Studies trying to establish the reasons why women refuse to undergo a reconstruction procedure found that 62% of the patients cited a lack of information regarding the reconstruction procedure as an important factor in influencing their decision [20].

Immediate vs. Delayed Breast Reconstruction

Whether we perform breast restoration surgery by using alloplastic or autologous material, we can opt for immediate reconstruction (at the same time as the mastectomy) or delayed reconstruction (weeks, years). A consensus is starting to take shape concerning the indications and contraindications for immediate and delayed reconstruction, with minor differences between different centers' protocols.

There is no absolute contraindication for breast reconstruction, but relative contraindications include morbid obesity ($BMI \geq 40 \text{ kg/m}^2$), and current smoking status. Senior citizens can benefit from breast reconstruction without any particular age-related contraindication [21].

Immediate reconstruction is the preferred choice for most patients, as it generates better aesthetic results, hence higher satisfaction rates [22]. The requirement for postoperative radiation therapy can be regarded as a relative contraindication concerning immediate breast reconstruction; in cases of T3 and T4 tumours, positive axillar lymph nodes and inflammatory breast cancer, it is recommended to delay the reconstruction procedures [21].

Delayed reconstruction is generally associated with lower satisfaction rates compared to immediate reconstruction, but long-term results reveal no differences related to the satisfaction levels reported by the two groups [23].

The majority of breast reconstructions worldwide uses *alloplastic material*. Although immediate reconstructions are preferred and studies reported higher satisfaction with immediate reconstruction than delayed ones [24], there are studies that highlight the incidence of higher complication rates associated with immediate implant-based procedures [25], but no difference in reconstruction failure rates related to the timing of the reconstruction [26].

When radiation therapy is required, opting for a prosthesis-based reconstruction is not advised, because of the multiple complications risks.

For autologous flap reconstructions, immediate reconstruction is associated with the advantage of fewer surgeries and better aesthetic results [27]. In delayed reconstructions, the skin is contracted, with thin and scarred skin flaps. Some studies found higher rates of complications in the delayed group, such as the risk of thrombosis [28], while others did not find statistical discrepancies concerning minor versus major complications related to the timing of autologous (free TRAM) breast restoration [29].

The immediate flap-based breast reconstruction might affect radiation delivery and alter the aesthetic results as well [30]; therefore, the patient should be aware of the possible risks. Recent studies reveal no statistically significant discrepancies when speaking of local recurrences, metastases or patient survival, whether a TRAM flap reconstruction or no reconstruction is done [31].

In an attempt to establish the best moment to proceed to a delayed reconstruction following post-mastectomy radiotherapy, when comparing results and complications, it was found that a 12-month delay after radiotherapy gave less complications, less vascular thrombosis and better results when using a free abdominal flap [32].

Studies reveal that women choosing to undergo a breast reconstruction procedure have a different socioeconomic status than those who refuse breast reconstruction, are wealthier [33], more educated, with greater access to medical services.

A study of more than 54,000 breast reconstructions found that immediate reconstruction enhances breast cancer specific survival [34]. A possible explanation lies in the fact that this type of reconstruction was chosen by younger women, diagnosed at an early stage, without lymph node involvement, and lower chances of receiving radiation therapy.

ALLOPLASTIC BREAST RECONSTRUCTIONS

The great majority of breast reconstruction (BR) worldwide is done with prostheses; over 76,000 implant-based BR (representing 79% of all BR procedures) were reported in 2011 in the United States [35]. Even though recent studies reveal a higher satisfaction rate with autologous reconstructions, up to 70-80% of BR are implant-based [36], although a decreasing pattern is observed mostly in specialized centers.

The explanation for this percentage is mostly due to the fact that free flap autologous reconstructions are done only in specialized centers that cannot support the great amount of reconstructions, and different BR options must be generally approachable. Other possible explanations might be shortened surgery time and hospital admission duration, cultural acceptance regarding implants, better reimbursement from insurance companies [37], and fewer contraindications from an oncological point of view [38].

Indications: Implant-based reconstructions are favorable in small breasted women with no or minimum breast ptosis [39] and good skin quality. They are also indicated for bilateral reconstructions [40] and patients diagnosed in early stages, preferably sentinel node-free [41].

Breast reconstruction using a prosthesis can be chosen while doing the mastectomy surgery (immediate), either by placing a tissue expander concomitant with the mastectomy to maintain the skin envelope coverage, followed by a permanent prosthesis (delayed) [42].

FACTORS THAT INFLUENCE OUTCOME AND SATISFACTION IN ALLOPLASTIC BREAST RECONSTRUCTIONS (TABLES 2, 3)

Timing of Reconstruction

Regaining consciousness in the early post-surgery aftermath and acknowledging an amputated breast is associated with great physiological distress, this being the reason why immediate restoration of the breast has the benefit of preventing the process [43], by recreating the volume of the breast and also the shape, to the patient's greater satisfaction [44, 45]. There are some limitations, however, such as the need for surgical revision in the years to come [46, 47]. As previously discussed, the timing of the surgery influences the satisfaction. Immediate BR is preferred when possible, as the inframammary fold is preserved, no skin contraction occurs and minimal scars are generated.

On the other hand, patients requiring radiation therapy [48] or possessing large breasts with advanced ptosis might benefit more from a two-stage reconstruction [49] or delayed reconstruction, as the expander will be placed right after or some time after mastectomy, in order to maintain the natural breast envelope proceeded by definitive implant.

Radiotherapy

It is documented that radiotherapy, regardless of the timing of administration, favors complications and implant failure risk [50], as well as lower satisfaction levels regarding surgical results, and a significant impact on the patient's physical, psychosocial and sexual wellbeing [51]. The highest dissatisfaction rates were associated with radiation therapy on immediately implant reconstructed breasts compared to delayed, as the radiation leads to capsular contraction [52]. Long-term felt pain post-radiation and capsular contraction [53] accompanied by the imperative secondary surgical procedures [54, 55] concluded in breast restoration failure [56, 57].

Breast implants nowadays can be chosen based on their content (saline or silicone), form (round or anatomic) and outer shell (textured or non-textured) [38]. With regard to form (round or anatomic), no unanimous opinion has been reached, while pros and cons and complication data have been found to be similar [58].

Although implant-based breast restoration is paired with great satisfaction [59], when considering content, studies indicate that silicone implants are preferred to saline ones by a vast majority of patients [60, 61], due to the more natural feel they generate as they are softer than saline implants.

In response to implant coating, textured shells were adopted as a solution for capsular contraction [62, 63]. Despite some controversy over the years [64, 65], textured implants have also proven their efficiency in keeping the implant in place [66], as well as not having a ripple aspect as seen often after long-term deflation of saline-filled implants [59].

Smoking is a well-known factor to increase surgical complications, more precisely in prosthetic BR. Smoking increases the risks of complications by 2-3 times compared to non-smoking patients, reaching a complication rate of 37.9%. Ex-smokers (up to 1 year after) also have higher complication rates [67].

Other factors, such as *obesity*, have been proven to increase the risk of complications at approximate twice for a BMI>30, compared to normal weighted women. Women with a BMI>25 prefer to undergo an autologous abdominal flap BR. Also *elderly patients*, those over 65 years of age, are prone to develop perioperative complications [26].

Breast restoration using a prosthesis is preferred by women under 40 years of age, compared to women between 40 and 60 years of age who prefer abdominally-based flap reconstructions [2, 68].

Concerning patient-related factors that might influence outcome and satisfaction, it was found that *diabetes* is not an independent complication predictive factor or implant reconstruction failure [50].

Immediately reconstructed breasts using prosthesis only and those combining implants and ADMs (Acellular Dermal Matrix) were equally appreciated by their recipients, with insignificant discrepancies regarding the final result between the two [69]. The combined method of reconstructed breasts lacked the natural sensation when compared to implant-based restoration, but the recipient's overall satisfaction was equal [69].

Limitations

It is known that breast implants should not be retained for a lifetime, that revision surgery and implant change might be needed. The decreased satisfaction with implant BR when compared to autologous abdominal reconstruction could be related to the complications and the possibility of secondary surgery that accompanies this procedure. Mild to severe capsular contracture is reported in numerous studies, with percentage varying between 2% to 83% [70], with increased chances in the irradiated groups [71]; reoperations for implant removal or replacement was found in 30% of cases, with a total reoperation rate of about 45-50% [72].

To conclude, patients with irradiated breasts, with multiple scars, with skin deficit, with poor soft tissue or with severe breast deformities should not undergo an implant-based BR alone. The procedures more suitable in these situations are either an autologous BR or a combination of an autologous flap, such as latissimus dorsi flap, that brings enough soft tissue to cover an implant.

AUTOLOGOUS BREAST RECONSTRUCTION

Restoring the breast from the patient's own tissues using flaps rather than alloplastic material has proven to be the generator of most satisfying results [73, 74], to such an extent that studies trying to objectively quantify the self-recognition (using functional MRI to assess brain activity) of one's DIEP flap reconstructed breast concluded few discrepancies in evaluating the natural and the restored breast [75].

In choosing a flap, the possibilities are numerous. Flaps for breast restoration can be pedicled or free, myocutaneous or cutaneous. Donor sites are also numerous, with the abdomen as the most frequently used.

FACTORS THAT INFLUENCE OUTCOME AND SATISFACTION IN AUTOLOGOUS BREAST RECONSTRUCTIONS (TABLE 2)

Table 2. Patient-related factors influencing breast reconstruction outcome, satisfaction and complications

	Alloplastic	Autologous
Radiation	• Capsular contracture • Infection • Wound-related complications • Lower satisfaction overall	• Poor cosmesis • Fat necrosis
Chemotherapy	• No influence (if waiting 6-8 weeks before reconstruction)	• No influence (no waiting needed)
Smoking	• Skin necrosis • Infection • Reconstructive failure	• Negative influence • Flap necrosis • Fat necrosis • Abdominal hernia
Obesity	• Reconstructive failure	• Flap complications • Donor site complications
Age	• No influence	• No influence
Medical Comorbidities	• Hypertension: pre-op complications; premature prosthesis removal • Diabetes Mellitus: no independent influence	• Hypertension: surgical complications; donor, receptor site complications • Diabetes Mellitus: infection; vascular disease; surgical and post-op complications
Prior Surgery	• Breast conserving treatment: capsular contracture; inferior esthetic outcome • Multiple scars on irradiated tissue: inferior outcome	• Abdominal scars: minor complications

Table 3. Surgical factors influencing alloplastic breast reconstruction outcomes and complications

	Alloplastic
Implant Properties	• SHAPE: No influence • CONTENT: silicone greater satisfaction over saline
Reconstruction Timing	• Greater satisfaction with immediate reconstruction
Single Stage Breast Reconstruction	• Direct-to-implant: lower aesthetic results
Use of ADMs, Autologous, Fat Grafts	• + ADMs: risk of seroma, reconstructive failure, infection • + AUTOLOGOUS: lower risk of implant related complications • + FAT GRAFTS: improve overall aspect of reconstructed breast; greater satisfaction with outcome; risk of fat necrosis, oil cysts, infection

Timing of Reconstruction

Autologous reconstructions, as the implant-based ones, can be immediate or delayed. Immediate BR, when possible, is preferred in autologous reconstructions also; it results in fewer interventions, good aesthetic results [27], better skin quality, and lower rates of free flap thrombosis [28]. Recent studies show that immediate reconstruction with TRAM flap does not change the rates of local recurrences, metastasis or patient survival when compared to no reconstruction. Furthermore, immediate TRAM flap BR does not interfere with long-term results, even when radiation therapy is necessary after mastectomy [31]. Still, patients are persuaded to first finish their radiotherapy and then proceed to BR, as this associates with better long-term results [76]. For optimum results, the appropriate delay should be at least 12 months.

Radiation Therapy

Even though numerous studies show that the immediate use of flaps does not interfere with cancer spread, recurrence or overall survival, the aesthetic results are altered when radiotherapy is involved.

When trying to compare different autologous flaps that received radiotherapy, no great differences were observed. A study that compared breast restoration using free DIEP flap to pedicled TRAM flap found similar fat necrosis rates in the two groups.

Smoking also interferes with autologous reconstructions results. Using a latissimus dorsi or TRAM pedicled flap in a smoking patient seems to have fewer complications [22]. Smoking was found to increase the incidence of necrosis rates in fat tissue and flaps. The predisposition to wound infection when using free TRAM flaps was also increased [77]. In pedicled TRAM flaps, smoking was found to increase the wound healing period, infections and flap complications. At least 1 month of smoking abstinence is necessary to increase the chances of free flap survival [78].

Other factors, such as *diabetes*, stir continuous debate. Diabetes is cited among the majority of contraindications for free flaps and even pedicle abdominal flaps. Studies that specifically compared results of free flap outcomes in BR did not find any differences in complications and outcomes for type I diabetes, type II diabetes or diabetes-free patients in 896 free TRAM flaps [79]. Another study of 1533 free flaps did not find diabetes to be an independent complication generator in breast reconstruction, but they found that diabetes is a risk factor in extremities free flaps reconstructions [80].

Obesity has also proven to generate up to 2 times more flap complications [81]. However, despite this complication rate, autologous BR is more suited to obese patients, as women with a BMI>25 are more likely to receive abdominally-based flaps [2], and satisfaction rates after this type of BR are similar to normal BMI patients [82]. In prosthesis-based BR in obese patients, decreased esthetic satisfaction was found, but there were no differences in satisfaction when autologous TRAM flaps were used for BR [83].

Choosing the Right Autologous Flap (Table 4)

Latissimus Dorsi (LD) Flap

The first flap described in the literature, more than 100 years ago, for breast reconstruction is the LD flap [84]. Its utility has been recognized, not only as autologous reconstruction, but also in covering implants in autologous and alloplastic reconstruction combined. If harvested with a skin paddle, it has the ability to compensate for skin loss [84-86] but, when used on its own, it offers a small restorative volume as it suffers atrophy, thus the recipient is preferred to be thin or small breasted [87, 88]. LD flap can be used to provide coverage for a prosthesis instead of pectoralis or serratus muscle with superior esthetic outcomes [89]. The introduction of ADMs on a large scale and perfected microvascular techniques facilitating free tissue transfer, accompanied by complications such as pain and seroma at the harvest site [90-94], shoulder girdle impaired mobility [95-97], together with torso contour alteration [88], lead LD flaps in breast surgery to fall from grace.

Long-term surveillance data state the requirement for secondary surgery in 10 years after breast reconstruction using combined LD flap and implant, in more than 50% of patients [98], restricting the use of LD flaps to limited cases. Statistically, over the past years, the use of LD flaps has been decreasing in favor of free flaps or allografts [89, 99]. When compared to acellular dermal matrix for implant cover, complication profiles have been similar, even though LD enjoyed better cosmetic results [100]. When compared to an abdominal flap, patients undergoing LD reconstructions were less satisfied than women receiving TRAM or DIEP flaps [101].

In terms of patient appreciation, long-term surveillance of LD flap use in breast reconstruction suggests great satisfaction from its recipients, data quantified using not only patient reports (BREAST-Q) but medical staff evaluation and computer analysis programs (BCCT.core) as well [87, 102].

All in all, even if cast to the background in favor of other techniques [89], the LD flap is cited among the “workhorse” flaps for breast restoration, with innovative use and perfecting harvest techniques [103] in addition to the ones we know.

Table 4. Surgical factors influencing autologous breast reconstruction outcomes and complications

	Autologous
Flaps	• Flap options: pTRAM, fTRAM, DIEP, SIEA, TUG, SGAP, IGAP, FCI, PAP, LD • No significant difference in complication incidence in free flaps vs pedicled • pTRAM vs free flaps: fat tissue necrosis; flap loss (total to partial) in obese patients • DIEP vs fTRAM: donor site morbidity, abdominal hernia, partial flap loss • SIEA vs fTRAM and DIEP: small pedicle diameter and length, small flap, risk of fat necrosis and thrombosis • Gluteal and thigh flaps: good option for slender, small breasted patients • High satisfaction with overall outcome and long term results
Reconstruction Timing	• Greater satisfaction and better aesthetic outcome in immediate reconstruction
Fat Grafts	• Better symmetry and cosmetic outcome

Abdominal Flaps

When choosing to undergo an autologous restoration of the breast, the most common site used in harvesting a flap is the lower abdomen [104]. Rather than implant reconstructed breasts, the autologous tissue offers the possibility of acquiring a more natural appearance and consistency for the restored breast [105]. At the same time, the patient's satisfaction increases when excess abdominal tissue is transferred in the process of autologous reconstruction [106]. Even though postoperative recovery is more demanding, secondary surgery is rarely necessary [2], so the appeal of this kind of reconstruction is explainable to active women of society.

The abdomen offers three major flap possibilities: the TRAM (transverse rectus abdominis musculocutaneous), the DIEP (deep inferior epigastric artery perforator) and the SIEA (superficial inferior epigastric artery).

The TRAM flap was the first to be introduced for breast reconstruction [107] 37 years ago. In time, the TRAM flap has suffered numerous alterations regarding its composition and tailoring as to limit donor-site suffering.

In 1992, *the DIEP flap* era began in breast reconstruction [108]. Over the years, operative technique refinement and perfecting has led to establishing the DIEP flap as the most elected breast restoration method using autologous tissue [104, 109]. Adding to its appeal is the possibility of solving chronic lymphedema in some cases by incorporating lymph nodes from the inguinal region in the tissue transfer process [110].

However, both TRAM and DIEP flap dissection damage the abdominal wall (TRAM by including muscle and DIEP by injuring the rectus abdominis muscle fascia), thus allowing the possibility of herniation, although post-DIEP herniation occurred in considerably fewer cases than post-TRAM herniation [111-113]. As a solution to the problem, the SIEA flap comes to mind, since it does not involve tampering with the abdominal wall muscular structure, by its adipocutaneous nature [88, 104]. Its limitation, however, lies in inconstant superficial epigastric artery presence and the reduced dimension, often insufficient for reconstructing a breast [109, 112, 114].

When considering patient satisfaction and quality of life, recent studies trying to quantify these parameters using BREAST-Q modules found greater appreciation of autologous abdominal flap breast reconstruction as opposed to prosthesis [115], also when compared to LD autologous reconstruction [101].

At the same time, when comparing pedicle TRAM flaps to free abdominal flaps, patients reported greater appreciation for the pedicle flap in the immediately postoperative period, with equivalent scores of satisfaction as time went by [116]. The offered explanation consists of operation timing, as pedicled flaps were chosen to restore breasts after skin preserving mastectomy followed by immediate reconstruction, whereas patients requiring adjuvant tumor-related treatment benefited from delayed reconstruction resulting in physiological distress that ended after breast reconstruction [116]. Another study comparing the outcomes of pedicle TRAM flaps to free abdominal flaps found that pedicle TRAM was associated with more flap necrosis than free abdominal flaps [117]. Comparison of donor site morbidity between pedicle TRAM and DIEP showed that TRAM patients needed abdominal closure with mesh in 44.2% of cases. Also, the hernia or bulge after pedicle TRAM flap was 21.2% as opposed to 3.1% for the DIEP patients [118].

Quality-of-life 5 years post-autologous breast restoration using the DIEP flap was found to be high among its recipients, even similar to that of the general population [119].

Gluteal and Thigh Flaps

Not all patients are candidates for abdominal flap breast reconstruction, as slender patients with no excess tissue on their lower abdomen are unsuitable for DIEP or TRAM flap breast reconstruction. To fulfill their wish for autologous reconstruction, the gluteal area and the inner thigh have proven to be more than suitable. Depending on the needed breast volume, a superior or inferior gluteal artery perforator (sGAP/iGAP) flap is suitable for slightly larger breasts whereas a transverse upper gracilis myocutaneous (TUG) flap is suitable for medium to small sized breasts [109, 120].

Introduced to the breast reconstruction field approximately 10 years apart, sGAP (1993 [121]) and iGAP (2004 [122]) offer the advantage of better projection to the reconstructed breast when compared to their abdominal alternatives [123]. The vascular pedicle provided by the iGAP is longer than the sGAP one, but can lead to asymmetric gluteal projection and infragluteal crease. Also, skin tone may differ, making them better suited for skin-sparing mastectomy reconstructions [123]. In order to preserve gluteal area symmetry, a double iGAP unilateral breast reconstruction has been described [123]. Concerning disadvantages, slight discomfort in the sitting position has been brought to attention in iGAP reconstruction cases [109].

Another reliable option regarding breast reconstruction when considering younger patients, presenting firmer breasts and less ptosis, is the fasciocutaneous infragluteal (FCI) free flap, which has been shown to offer adequate volume even in slender patients [124].

The TUG flap, used in breast reconstruction since 2004 [125-127], offers a good option for small to medium breasted patients, but requires a minute and laborious dissection to isolate the vascular pedicle, as attention must be paid to the saphenous vein and inguinal lymph nodes in an attempt to avoid lymphorrhea [128] and to the the posterior cutaneous nerve of the thigh to preserve thigh skin physiological sensation. In response to this predicament, the profunda femoris artery perforator flap was described recently [129], its pedicle trajectory allowing the avoidance of lymphatic structures; it also offers a longer pedicle than the TUG flap, with similar characteristics [129].

As microsurgical skills are more and more refined among surgeons, various combinations of free flaps can be used for remarkable cosmetic outcomes, even in bilateral breast reconstruction, offering the surgeon the possibility of molding the flaps to create the desired and suitable shape for every patient opting for autologous breast restoration, regardless of the BMI.

CONCLUSION

- Breast reconstruction represents an immensely important step towards physical and mental healing in the aftermath of breast cancer.

- Providing patient tailored information, presenting the patient with a wide pallet of options and leading her towards the best personal fit, assisted by patient reported reception of reconstruction, can lead to increased level of satisfaction with the results [130].
- Educating the patient in knowing what to expect in the immediate post-reconstruction period and leading the patient to realistic expectations sets the ground for a satisfying outcome.
- Immediate reconstruction when opposed to delayed reconstruction generates greater levels of satisfaction, but long-term results suggests no difference between the two groups.
- Skin and nipple preserving mastectomies followed by immediate reconstruction are favored.
- In case of alloplastic materials, direct-to-implant reconstruction, covering the implant with ADMs/synthetic meshes, and respecting the integrity of pectoralis and serratus muscles enjoys better reception.
- When comparing the combination of ADMs with implants versus latissimus dorsi flaps with implant, patients reported better aesthetics with the second option.
- Autologous reconstruction is reported to enjoy better long-term satisfaction as no secondary surgery is required in the majority of cases.
- The lower abdomen is the go-to donor site and the DIEP flap the go-to flap for long-term satisfaction.
- In obese patients, implant-based reconstruction was met with lower levels of satisfaction regarding cosmetic outcome in comparison to autologous reconstruction.
- Delayed autologous reconstruction is associated with better outcomes in patients requesting radiotherapy.
- Complications throughout the breast reconstruction process leads to lower overall satisfaction outcomes, especially if associated with requiring secondary intervention.
- Long-term surveillance (more than 5 years) revealed that QOL in patients with DIEP flap reconstructed breasts is similar to general population QOL.

All this being said, there are cases when the esthetic outcome pleases the patient more than the surgeon [131], suggesting the utmost importance of breast restoration treatment for cancer patients, as the esthetic aspect of the matter is not the most appraised one [69].

Chapter 176

WHAT COMES AFTER A FREE FLAP FAILURE FOR BREAST RECONSTRUCTION?

ABSTRACT

Free flaps for breast reconstruction are among the most used procedures nowadays. Most common free flap procedures are DIEP, SGAP, IGAP, FCI and gracilis. The success rates in experienced centers range between 93-97%. Failure of a free flap can have many causes and the result can be a disaster for the patient, with loss of the new breast and donor area scars or other complications. When a salvage procedure fails, the question raised is what to do next.

Choosing an implant or expander-based procedure can be a good choice for these patients. Choosing a second free flap can be a risky procedure, taking into consideration the psychological effect of another failure. When the gluteal area or thigh is used as a donor site, the other one can be used for harvesting. If DIEP was used, this donor area cannot be used again, and other locations should be selected.

The cause of the failure should be carefully evaluated. When prothrombotic systemic disease is ruled out and the quality of recipient vessels are suitable for anastomosis, a second free flap can be used.

Keywords: breast reconstruction, free flap, implants, failure, obesity

INTRODUCTION

There are many possibilities for breast reconstruction (BR), including breast silicone implants or expanders, or flaps, or a combination of these. Pedicled flaps, such as the transverse rectus abdominis muscle (TRAM) was widely used a few decades ago. With developing microsurgical techniques, free flaps are more often used nowadays, and perforator free flaps are used more frequently. Among the most used are the deep inferior epigastric perforator (DIEP), the gluteal artery perforator (GAP) flap, and the fasciocutaneous infragluteal (FCI) flap.

Replacing tissue with tissue-like is of great importance in BR. The chances of long-term complications are reduced for vascular free flaps compared with implants [1-3]. Success rates in breast reconstruction exceed 93-97% in experienced centers. There is no doubt that requests for BR are increasing yearly.

Patients with a family history of breast cancer or have BRCA mutations are interested in prophylactic mastectomy on the contralateral side [4-6]. Autologous tissue BR has the advantage of offering better symmetry, especially in cases with breast ptosis. The DIEP flap is the workhorse for free flap BR and its use also improves the abdominal aspect. While most free flap BR are successful in most centers, a total failure is disappointing both for the surgeon and for the patient. When failure occurs, some authors [7] prefer reconstruction with a prosthetic device which has a higher chance of success. In bilateral cases, using a free flap for the contralateral side offers an easier opportunity for tailoring the flap and a better match with the prosthetic side.

In a retrospective study conducted on 2306 free flaps for BR, obesity, hypertension or prolonged operation were associated with flap failure [8]. A hidden patient hypercoagulability predisposition can lead to multiple free flap failures [9]. A hematological workup can reveal anomalies of protein S activity, Factor VIII, plasminogen activator inhibitor or antiphosphatidyl antibodies. These tests are not done routinely before any free flap procedure. However, when a complication is encountered, all these parameters needs to be evaluated.

A review of the morbidity of BR in obese patients was performed by Fisher et al. [10]. In a study on 15937 BR performed between 2005 and 2010, obesity was present in 27.1%. Grade III obesity was encountered in 4%. It is interesting that the author did not find a difference in first month complications between autologous and implant-based procedures [10]. However, obese patients have a greater perioperative risk and more medical complications. In a study by Garvey et al on 990 BR in obese patients, 548 had free flaps and 442 had implant-based BR [11]. In this study, the authors found a higher failure rate in the implant-based group (15.8%) than in the free flaps group (1.5%).

Efforts to analyze several parameters for free flaps have been made by experienced surgeons in order to prevent complications and elaborate a strategy for reconstruction. Damen et al. [12] evaluated 406 consecutive free flaps (164 used for unilateral and 121 for bilateral BR). The most common recipient vessels for free flap BR are the internal mammary ones [13, 14]. For the DIEP flap, many authors use a single perforator and consider it sufficient for perfusion. Damen et al. [12] is in favor of using a single perforator when the vein diameter is greater than 1.5mm. Nahabedian et al. [15] considers a single perforator flap safe if the diameter is greater than 1.5mm and the flap weight is less than 750gr. Several recommendations have been described by experienced surgeons to reduce complication rates.

Blondeel [16] prefers a single or two perforators located at the musculocutaneous junction. The larger the perforator, the greater the chance for flap survival. When a large perforator is present, it is preferred to two small perforators [17].

The best solution to overcome a failed BR has not been established and authors' opinions vary. Rao et al. [7] reported a 3.5% failure rate on 342 free flaps where reconstruction with tissue expanders and implants was performed. An average of 2.25 additional procedures were necessary in these cases to achieve the final result. In a study on 688 patients, Hamdi et al. [18] reported 14 patients who required tertiary BR. Eight patients had a second free flap, and two required another reconstruction due to failure. A failed solution cannot be solved with the same way of thinking. Identifying the cause of failure as precisely as possible can lead the surgeon to choose the best next solution. According to Hamdi et al. [18], a second free flap can be offered as a solution for a failed one. When an abdominal area was used, other donor areas, such as the buttock or thigh, are good options.

Figure 1A. The mastectomy area in a young female with no abdominal fat deposits.

Figure 1B. The donor area for FCI flap - the left side was used.

Figure 1C. The flap.

Figure 1D. The flap became congestive on the second day after surgery. A salvage procedure was tried but was only partial successful.

Figure 1E. A few weeks after surgery with a partial flap loss.

Figure 1F. Six months after - the remaining flap became fibrotic and was removed.

Figure 1G. A second free flap was used from the contralateral buttock - 18 months after reconstruction.

Figure 1H. The donor area 18 months after surgery.

According to Mohan et al. [19], DIEP is the first choice for BR in a failed or unsatisfactory implant reconstruction. Implant-based BR is a useful and very common method. Unfortunately, there are cases with unsatisfactory results or long-term complications after implant- or expander-based procedures [20, 21]. The most common late complication is by far capsular contracture [22]. The free flap BR has the advantage of having good long-standing results and fewer revisions compared with other methods.

In a retrospective analyses of 902 free flaps for BR, Baumeister et al. [23] identified 13 patients who had a second free flap after a primary failure. After analyzing possible causes of the failure, the re-operative strategy was changed. For most, more proximal recipient vessels or different recipient vessels were used. A different flap type was used in these cases and success was achieved in 11 of 13 patients. Reconsideration of a second free flap procedure should be done after carefully analyzing the cause of the failure, using a sensitive approach to the patient, and changing the surgical strategy [23]. Massenburg et al. [8] used a contralateral latissimus dorsi (LD) flap for secondary or tertiary reconstructions.

Some authors are in favor of a second tissue transfer after a primary failure [24], while other authors are in favor of this strategy even though it concerns other regions of the body. In a large number of free flap cases (3361) performed in the head and neck, after careful analysis of the outcome of the failed free flap, Wei et al. [25] performed a second free flap and found it reliable for most patients.

Choosing the best solution after a free flap failure is not a simple task, based solely on the surgeon's preference (Figures 1A-H). If the patient is very anxious, we suggest an implant-based solution. In cases with hypercoagulability, such as anticardiolipin antibodies and free flap failure, we suggest an implant only or an implant combined with a LD pedicle flap.

ABSTRACT

Nipple areolar reconstruction (NAC) progressed in parallel with breast reconstruction. Being a part of the complex process of the reconstruction of the breast, it also represents an important asset in the evaluation of the overall quality of this process. Patients associate this stage with the end of the treatment and with a sense of completeness.

It can be done during the primary or secondary breast reconstruction or later. Ideal reconstruction of the NAC requires symmetry in position, size, shape, projection, texture, and pigmentation.

Numerous techniques for nipple-areola complex (NAC) reconstruction are described. NAC reconstruction techniques comprise of composite nipple grafts, local flaps, flaps with autologous graft augmentation, flaps with alloplastic augmentation and flaps with allograft augmentation.

The local flaps are the most frequently described techniques for the nipple reconstruction with no significant difference in complications' rate among the various types of techniques. In literature, complications in nipple reconstruction are almost 50% after graft, 8% after local flap, and 5% in case of flaps with autologous graft/alloplastic/allograft augmentation, while complications in areola reconstruction are 10% after graft, and less than 2% after areola tattoo. Flaps appear to be more reliable than grafts in nipple reconstruction, while tattoo is thought to be safer than graft in areola reconstruction.

The loss of projection is considerable (45%-75%). Overcorrection of 25-50% of the desired result is advisory when adopting local flaps, in order to prevent loss of projection.

* Corresponding Author's Email: Dragos Zamfirescu; dragoszamfirescu@gmail.com.

The use of flaps with autologous graft/alloplastic/allograft augmentation (cartilage, fat, calcium hydroxylapatite, acellular dermal matrix, collagen) showed a minor loss of nipple projection but may expose to a relative increased number of postoperative flap necrosis.

Keywords: nipple reconstruction, flap, cartilage, skin graft

INTRODUCTION

Reconstruction of the nipple and the areola was first introduced as a concept in the 1940s and has evolved ever since in parallel with reconstruction of the breast following cancer treatment, leading to the development of countless techniques, but lacking a complete list until now. The nipple-areola complex is the last phase of breast reconstruction, albeit a very important part in this elaborate process. It is associated with a sense of completeness and of reaching the last stage of the treatment. It is usually performed in the second or third stage of the process, frequently after radio- and chemotherapy have been performed. Reconstruction has to take into consideration symmetry in all aspects: position, size, texture, shape, permanent projection and pigmentation. Nipple reconstruction is usually the first phase and can be undertaken using local flaps, grafts or flaps consisting of autologous graft, allograft or alloplastic augmentation, while the use of tattooing and of skin grafting have been described for areolar reconstruction as frequent and easy possibilities. Although considered a simple surgery, reconstruction of the nipple and areola has important psychological aspects when evaluating the quality of the entire reconstructive process [1-4].

HISTORY

The history of the nipple-areola complex (NAC) reconstruction began in the 1940s with Adams using the labial minus grafts for reassembling [5, 6]. Evolution followed some 30 years later with the nipple-sharing concept introduced by Millard which harvested tissue from the contralateral nipple [7]. This journey of progression over time included diverse grafts (toe pulp, cartilages) [8], then flaps composed of local flaps (such as the T flap in the 1980s) [9], culminating with the 1980-1990 period when the traditional flaps were defined, such as the F flap, Z flap, star flap or skate flap. Finally, synthetic materials have been used alongside allografts in the newest techniques.

INDICATIONS

Normal Areola Characteristics

One of the first aspects to be taken into consideration when planning a nipple-areolar complex reconstruction is the aspect of the normal areola. The normal areola is generally placed where the most projection can be achieved on the reconstructed breast. Several

measurements and aspects should be taken into consideration, such as size, shape, diameter and color, adapting them to the contralateral breast [10].

Measurements should be made so as to symmetrize the two NACs, adapting the distance between the areola to the inframammary fold and the distance between the nipple and the notch, matching those of the normal nipple [11].

The real challenge arises when a bilateral reconstruction is required. In this case, several standard numbers are taken into consideration: an areola medium diameter of 4 cm, with a nipple of 1.3 cm in diameter and 0.9 in projection [12].

Timing

One of the most important aspects of the problem is time. The timing of the operation results from a multidisciplinary decision. Frequently it is performed 3-5 months after the last operation, as adjuvant therapy may hinder correct healing [13].

Patient Selection – A Multidisciplinary Decision

The whole treatment process results from the decisions made by a multidisciplinary team that consists of an oncologist who conducts the work and the surgical team formed by a general surgeon and/or a plastic surgeon [10].

Many patients are candidates for a reconstructive procedure. Most surgical operations performed for breast cancer use a skin-sparing mastectomy which frequently leads to the loss of the nipple, with an important psychological impact by affecting the aesthetic aspect and the sense of completeness [3].

Although nipple-sparing mastectomies provide a big upgrade in the psychological matter, they are rarely performed mostly due to the characteristics of the tumor, such as its adjacency to the nipple or its size.

Surgical Techniques

Surgical techniques vary, based on the possibilities offered by the type of the previously practiced mastectomy (nipple-sparing versus skin-sparing), the quality of the local skin, the presence or absence of scars, the excess and the aspect of the contralateral NAC complex, the surgeon's preference and last, but not least, the patient's choice [10, 14].

Achieving Long-Lasting Projection

Representing perhaps the ultimate objective of the NAC reconstruction, achieving long-lasting projection is the result of the action of two factors: the flap's contraction and the retraction forces of the local tissues that act upon the flap. The first is an inevitable effect, taking place to different extents from patient to patient but leading to loss in projection and/or

volume. The second can be influenced by wisely choosing a variant with a subdermal pedicle which releases the flap from the adjacent tissues and provides vascularization through the subdermal plexus, which is a far better option than the vascularization provided by the subcutaneous tissue or by scarred or previously irradiated tissues [1].

Nipple Projection Loss

The main issue in the reconstruction of the nipple is the postoperative loss that may occur, either in terms of projection or of volume, regardless of the technique used [15]. Consequently, it is recommended that the reconstructed nipple be double the size of the intended future form [16, 17].

RECONSTRUCTION OF THE NAC

Reconstruction of the nipple-areolar complex can be divided into its two main components: reconstruction of the areola and reconstruction of the nipple [1].

I. Nipple Reconstruction

If the volume of the contralateral nipple is big enough, it can be used as a graft for the future nipple. Otherwise, the preferred option is that of a local flap, such as the F flap, the Z flap, the skate flap or the star flap.

1) Composite Nipple Graft

Amongst the different procedures used for nipple reconstruction, the nipple-sharing technique remains a frequently used option when the contralateral nipple is prominent [5, 7]. Taking advantage of the fact that it uses the same kind of tissue, it represents a good option when a 5-6 mm projection excess is present, making these patients the ideal candidates [10].

The first phase of the operation consists in performing de-epithelialization of the new site for the nipple. Then the distal half (40-50%) of the existing nipple is removed and sutured at the site of the new nipple, while the donor nipple can be closed by using interrupted sutures covered by a tie over or purse-string suture. The last step is reconstruction of the areola which can be harvested from the contralateral one if there is an excess of tissue or from other sites (i.e., the inner thigh) [18, 19] Figure 1.

This is a suitable technique in cases of large nipples. Above all other surgical options, it best matches the attributes of the contralateral nipple when it comes to shape, structure, color or long-term projection [20].

Unfortunately, the use of this procedure is sometimes limited, mostly because of patients' reservations considering potential complications, such as morbidity of the donor site or discomfort for the patient, fear or unacceptance of contralateral surgery or decrease in that nipple's sensation. Also, surgeons seem loathe to use the healthy nipple because of the risk of morbidity, including pain, numbness or scarring [20].

Comparing the reconstructed nipple to the other one, it needs to be mentioned that overall satisfaction was good. In a study performed on 57 patients, Zenn et al. found that the overall appearance satisfaction was high (in 96% of patients). The same study proved a small decrease in sensation, 47% in the donor site lot weighed it to be normal, compared to 35% of the patients who had their nipples reconstructed. The largest discrepancy lay in that of the comparison between the erectile functions of the nipples, with 87% of the patients declaring that the donor nipple had normal erectile function, compared to only 42% of the patients who declared that they had erectile function 3 months after the operation [21].

Figure 1. Nipple reconstruction with composite graft. A. Harvesting the composite graft from the contralateral nipple. B. Closing the donor site. C. Deepithelialization at the position of the new nipple. D. Suturing of the composite nipple graft.

2) Traditional Flaps

The local flaps are the most frequently described techniques for the nipple reconstruction with no significant difference in complications' rate among the various types of techniques. In literature, complications in nipple reconstruction are almost 50% after graft, 8% after local flap, and 5% in case of flaps with autologous graft/alloplastic/allograft augmentation, while complications in areola reconstruction are 10% after graft, and less than 2% after areola tattoo [4]. Flaps appear to be more reliable than grafts in nipple reconstruction.

a) Skate Flap

Initially described in 1984 by Little, the skate flap is a widely used traditional flap, thus leading to multiple attempts over time to modify it. Taking into consideration the fact that one of the important aspects in reconstruction is symmetry, the skate flap is a good option when a projected appearance is desired, offering a long-lasting effect [22, 23].

The design of the flap consists in a central axis, a line that is tangential to the base of the nipple. It is recommended to rotate it so as the line does not include the flap's limbs or its central part [23]. The line, which also represents the diameter of the new areola, will be the base for the flap. Its length should be three times that of the nipple circle. Afterwards the line is split into three and a semicircular line that unites the two edges of the line is drawn. The

dissection begins from the lateral third progressing towards the center of the flap, from thin to thick, including a layer of approximately 7-8 mm of fat in the middle part of the nipple, thereby offering bulk and vascularization to the nipple [10, 23] Figure 2.

Special care must be taken not to dissect beyond the base of the flap. Subsequently, the two lateral thirds, or the wings of the flap, are rotated, encircling the base and then sutured one to the other. The last phase of the nipple reconstruction is the suturing of the central third to the other two-thirds [22, 23].

The conventional design consists of the de-epithelialization of the rest of the areola and covering it with a full-thickness graft [24, 25].

Having a good long-term projection rate over time attested to by multiple studies, the skate flap represents a widely used flap variant for reconstruction of the nipple [10]. When it comes to disadvantages of using the skate flap, nipple projection loss should be mentioned, varying from 40% to 75% [26, 27].

Figure 2. Skate flap. A. The superior part is deepithelialized. B. The wings of the skate are split thickness dissected and the central part is elevated with dermis and fat. C. Closing of the donor defect of the body. D. The wings covered the body to form a cone.

b) Star Flap

The star flap consists of three wings with the same base, beginning from a central point. As in the case of the skate flap, the width of the central wing establishes the nipple's width. The dissection begins from the lateral flaps, raising them carefully as to include subcutaneous fat, continuing to the central wing [22]. One of the lateral wings is rotated around the base of the nipple and sutured into position. Then the other wing is also rotated, suturing it to the base of the previous one. In the final phase, the central wing covers the previous two, forming the tip of the reconstructed nipple. The final aspect results in a T scar [28] Figure 3.

Although it is a good option with excellent results, it has the downside that, due to its final form, it may lead to skin ischemia, postponing the curative process. Another noteworthy disadvantage of the star flap is the lack of projection [10, 29].

Figure 3. The rays of the star are elevated including subcutaneous fat tissue. One of the lateral wings is rotated around the base of the nipple and sutured into position. Then the other wing is also rotated, suturing it to the base of the previous one. The central wing covers the previous two, forming the tip of the reconstructed nipple.

c) F Flap

An alternative for nipple reconstruction, the F flap is a good option when the contralateral nipple cannot be used, either because it is too small or because the patient refuses, or if the cancer was bilateral. It consists of an adipocutaneous flap which has two limbs and permits primary closure. The two limbs, which are vascularized from the same central base, are then folded into each other. The two limbs can be created asymmetrically based on the new nipple's size [30, 31] Figure 4.

Figure 4. A, B are side flaps. C is the central flap, covering the nipple. The tip of the A flap is sutured to point E. The tip of the B flap is sutured to point D.

In the first phase the selected area is tattooed, after which the two flaps are raised with all the layers of the skin, including the underlying adipose tissue used for the best results in nipple volume. The volume increases proportionally to the thickness of the skin. The two limbs are crossed, usually placing the longest one more inferior than the other [30, 31].

d) Z Flap

The Z flap has been described in several pathologies, although it is a rather new technique. A good option for treatment of the inverted nipple [32, 33], it is also employed when the quality of the skin is not optimal or when the local circumstances are not favorable for an F flap [30]. In addition, it has been described as an alternative in the reconstruction of the nipple.

Although it has two limbs, as the previous flap, each of them has its own pedicle. Two separate pedicles translate into a more reliable vascularization, thereby lowering the possibility of necrosis. The areola's position is set and, following the same manner as in the case of the F flap, it is tattooed in the new spot [30, 31].

The design of the flap consists of two pedicles equal in width and in distance one from the other and with the future nipple [32]. The flaps are raised similarly to the F flap, in full-thickness, after which they are sutured directly one to the other, being careful not to roll nor plicate them [33]. An important aspect to take into consideration is the thickness of the two limbs which should be equal to half of the future nipple [30] Figure 5.

There are several complications which may occur at some time after the operation, such as: initial inadequate nipple projection or loss of nipple projection over time, necrosis (a rare complication that may occur if one of the two pedicles is insufficient), or fading of the areola [30, 33].

Figure 5. Z. The two pedicles are equal in width and in distance one from the other and with the future nipple. The flaps are raised similarly to the F flap, in full-thickness, after which they are sutured directly one to the other. The thickness of the two limbs which should be equal to half of the future nipple.

e) C-V Flap

The name of the flap describes it accurately. This flap is formed of three limbs, the V representing the shape of two identical limbs placed one opposite to the other, both starting from the center of the flap. The third limb is C-shaped or has a circular display with its diameter created so as to have the same width as the V parts [22] Figure 6.

Figure 6. A, B. The two lateral wings are elevated including subcutaneous fat tissue. One of the lateral wings is rotated around the base of the nipple and sutured into position. Then the other wing is also rotated, suturing it to the base of the previous one. The central wing covers the previous two, forming the tip of the reconstructed nipple.

The two V flaps will be the foundation of the nipple, offering projection. They are sutured together in a similar manner to the skate flap by rotating them along the future base. The C part is placed over these two, forming a rounded tip [22] Figure 7A-D.

Several studies have proven the good overall results of the C-V flap [34, 35]. Losken et al. proved maintaining of the projection at 5 years after reconstruction with an 81% overall satisfaction rate, while Valdatta et al. showed that, although a 32% projection loss was noticed after a year with a 17% increase in diameter, the volume of the neonipple was maintained.

Figure 7. A-D. Nipple reconstruction by the CV (CU) flap. Preop drawing of the flap and 8 months postop result.

3) Purse-String Flap Techniques

These types of flaps have the advantage of creating projection of the NAC complex by mobilizing the adjacent breast tissue. There are several of these procedures, such as the bell flap, the top hat flap or the double opposing periareolar/purse-string flap [36].

The *bell flap* was first described in 1996 by Eng. Named after its design, it facilitates slight areolar projection by suturing it in a purse-string manner [37]. Since its effects are transitory, with a possible projection loss of up to 73% after 1 year, the use of the bell flap has been actively limited to cases of small contralateral nipple projection [26].

The *top-hat flap* is not a true flap on its own. This technique implies the placing of four incisions, 2-4 mm one from the other. The projection of the nipple is established by the tension formed from a nonabsorbable string suture that passes from one incision to the adjacent one. Gamboa-Bobadilla et al. found this technique to be successful with a 6 mm nipple projection 18 months after the operation and a 90% overall reconstruction satisfaction [38].

The *double opposing periareolar flap* is derived from the skate flap. It was designed to offer both projection of the nipple and good scarring of the donor site. This technique elevates the lateral wings with slim layers of fat, while the central part is elevated with subcutaneous fat so as to grant projection [22]. Particular to this flap is the fact that the areolar contour is incised, allowing the areolar flaps to glide along the subcutaneous layer. Subsequently, the nipple is formed in a similar manner to those described before. Shestak's result in a study conducted in 2007 described no flap losses and no dehiscence. Nipple projection was constant with comparable results to those of the skate flap [39, 40].

4) Flaps Adjacent to Scars

Unlike the previously mentioned flap techniques, these flaps are designed to avoid compromised blood supply scarred tissue. Several of these flaps are the S Flap, the Double Opposing Tab Flap or the H Flap [10].

They consist of the creation of a circle with a diameter three times the size of the new nipple, which centers it. Afterwards, having the mastectomy scar as the central line, the different letters or shapes are drawn, leading to the formation of two identical flaps. They are then lifted and sutured, beginning from the base and ending at the tips. The next step implies the de-epithelization for the future areola which will be harvested and processed to meet the required shape [10, 30].

These flaps are a good choice for reconstruction, being a durable option over time, especially in terms of nipple projection [41].

5) Flaps with Autologous Graft Augmentation

This concept was introduced in an attempt to overcome the main problem of projection loss after local flap reconstruction. The alternatives include the use of fat or cartilage grafts [1, 42].

Fat grafting is an easy and increasingly popular technique. It harvests fat from the abdomen or from other regions, processing it and injecting it into the location of the future nipple which was previously drawn. After some time, the fat is resorbed and then the flap can be formed and sutured. This type of grafting is particularly useful for patients with thin subdermal fat [43].

Cartilage grafts offer good nipple projection and represent a rather simple alternative. They can be harvested either from the costal cartilage (Figure 8 A-D) or from the ear and then covered by a skin graft or a flap. Although it is believed that they offer long term projection [34, 35], cartilage grafts are not widely used and accepted due to donor site morbidity.

Guerra and colleagues proved excellent results in their study of 454 patients which used a costal cartilage graft and an arrow flap. Their patients lost only 4% of the cartilage graft due to ischemia or infection [44].

6) Flaps with Alloplastic Augmentation

Being one of the newest techniques employed for nipple reconstruction, this method uses materials such as calcium hydroxyapatite or hyaluronic acid, which provide a durable projection but, being non-self, may lead to infection and exclusion [3, 45, 46].

7) Flaps with Allograft Augmentation

Representing a top-of-the-generation product, the acellular dermal allograft is an increasingly popular method for nipple reconstruction as it has the best properties of an implantable material, with little to no rejection or resorption, rarely leading to infections and having a small projection loss [1]. The material is cut according to the required size, rolled upon itself, and then sewn to the adjacent tissue [47, 48].

An alternative to the previous allograft augmentation techniques is the Cook nipple, a cylinder forged to erase size errors which could lead to inequality [1].

Figure 8. A-D. Nipple projection with costal cartilage graft harvested on the time of breast reconstruction and banked in the inframammary fold pocket.

8) Loss of Projection

The loss of projection is considerable (45%-75%). Overcorrection of 25-50% of the desired result is advisory when adopting local flaps, in order to prevent loss of projection. The use of flaps with autologous graft/alloplastic/allograft augmentation (cartilage, fat, calcium hydroxylapatite, acellular dermal matrix, collagen) showed a minor loss of nipple projection but may expose to a relative increased number of postoperative flap necrosis [4].

II. Areolar Reconstruction

The two most commonly performed techniques for areolar reconstruction are tattooing or skin grafting, or a combination of the two [1]. Skin grafting, when employed, is usually performed at the same time as the nipple reconstruction and has the advantage of a similar texture to the contralateral nipple, while tattooing is usually performed 6-8 weeks later than the nipple reconstruction [1, 49].

1) Skin Grafting

The full-thickness graft is the choice when it comes to skin grafting. It has to meet the required size of the reconstructed areola. The donor site from which it can be harvested is usually the inguinal crease, although it can also be gathered from the contralateral areola, the retroauricular region, the upper region of the internal thigh/groin region, the inferior abdomen, or whenever there is excessive breast skin [50].

Following the harvest of the graft, the next required step involves the processing of the recipient site by de-epithelization that serves as a reliable base for the graft. The graft is then binded to the bed, using interrupted, nonabsorbable sutures [51].

Skin grafting has the advantages of providing an aspect that resembles that of a normal areola; it has the required texture, it is normally pigmented and it has a wrinkled surface [1].

2) Tattooing

Tattooing may be the first choice in the reconstruction of the areola [52]. Although it may seem less natural, it can be preferred as it has the advantage of not requiring a donor site (Figures 9-11). In most cases, unilateral tattooing is used when the color is easy to reproduce, and bilateral in cases of pale areolae. Usually it consists of a mix of colors (based on titanium oxide and iron) [53, 54] tattooed successively which best reproduce the aspect of the areola, avoiding a less natural effect of the reconstruction. Tattooing is performed first if the nipple is reconstructed using a graft but, in the case of using a flap, the harvest site will be tattooed first, the rest after skin closure [1]. There are times when tattooing is recommended to be done several weeks after the nipple reconstruction, with the mention that it may be required to be a tone darker because the color fades a bit in time [55].

Special care must be taken with the technique used. Placing the ink superficially leads to its loss, while placing it deeper results in the macrophages disposing of the ink. Either way, the result is premature pigment fading [55]. Furthermore, the sterility of the operation is also an aspect, as it may lead to viral transmission or disease.

The normal evolution after this intervention is performed is that of sloughing and crusting which may go on for as long as 3-5 days. It is recommended that the area be kept moistened with dressings changed daily [1].

CONCLUSION

Reconstruction of the nipple-areolar complex is the last step in breast reconstruction. It is associated with a sense of completeness and of success of the whole process. In order to achieve the best results, it must have regard to achieving symmetry with the contralateral NAC complex, placing them in the correct spot, respecting the correct size and color, in a “like to like” manner, preserving the results in time with the least nipple projection or volume loss.

Classically it is formed in two steps, the first being the nipple reconstruction, and the second being the areola reconstruction, performed either by tattooing or by using a skin graft, keeping in mind that the most common complication to counteract is the loss of projection and/or of volume.

Although, in chronological order, reconstruction of the nipple-areolar complex is the last after several other steps, it may be the most important one, being correlated with overall patient satisfaction.

Chapter 178

DEALING WITH COMPLICATIONS AFTER FREE FLAP BREAST RECONSTRUCTION

Raluca Sobec^{*}, Ioana Tichil and Lucian Fodor

Plastic and Reconstructive Surgery Unit, Emergency County Hospital,
Cluj Napoca, Romania

ABSTRACT

Breast reconstruction using free flaps is a procedure often performed by plastic surgeons. Like any other procedure, it is not without complications, which may occur whether it is an immediate or delayed, unilateral or bilateral reconstruction, with or without pre- or post-operative radiotherapy, in obese or smoking patients. Both the clinical setting and the surgeon's experience are closely related to the rate of these complications. Complications may imply hematomas, infections, vascular impairment, partial or total flap loss, wound dehiscence, hypertrophic scars or donor site complications. More specific to the use of microsurgical techniques are vascular complications: arterial or venous thrombosis and venous congestion.

How do we avoid complications and, if despite all methods of prevention, complications arise, how do we deal with them? The most severe and feared are vascular complications. If they occur, a challenging decision must be made: do we "watch and wait", use conservative methods to prevent impairment, or return the patient to the operating room. Timing of this decision by balancing clinical and objective findings will be the focus of this chapter. For instance, hematomas can lead to external vascular obstruction, and unrecognized or delayed recognition of vascular thrombosis will lead to partial or even total flap loss. Sometimes, partial flap loss is more challenging to deal with in the long-term than total flap loss.

What we intend to highlight in this chapter are: risk factors leading to higher rates of complications, early signs of complications, ways to monitor postoperative patients, and a systematic approach to treatment.

Keywords: free flap, breast reconstruction, complication, flap failure

INTRODUCTION

Although breast reconstruction is an ever-expanding field and the overall number of procedures has increased, still less than half of mastectomy patients undergo reconstruction [1]. Breast reconstruction can be performed either as an immediate or a delayed procedure. Currently, the most common is implant-based because of the short operating time, quick recovery and no donor site complications [2]. On the other hand, autologous breast reconstruction, despite the greater risks involved, provides higher levels of patient satisfaction due to the natural shape and consistency of the reconstructed breast, along with long-lasting esthetic results [1]. A wide range of complications associated with this procedure has been reported, with rates varying across different studies. Early complications occur within 30 days [1] of the procedure, such as edema, hematoma, vascular complications, infection and wound dehiscence, whereas delayed complications occur after 30 days, such as hypertrophic scarring and donor site complications. Avoiding complications is primarily a process of thorough patient selection based on an extensive knowledge of the risk factors involved and choosing the optimal reconstructive procedure, well-timed within the clinical setting.

DEALING WITH RISK FACTORS: ANALYSES AND PROPHYLAXIS

A wide range of free flaps can be used for autologous breast reconstruction, yet the most frequently employed are the abdominal-based ones, such as the deep inferior epigastric perforators (DIEP) flap, the muscle-sparing transverse rectus abdominis muscle (TRAM) flap, and the TRAM flap. Risk factors implicated in performing these procedures have been extensively researched and varying data have been reported. Risk factors can be either patient- or procedure-related.

Patient-Related Risk Factors

Radiation

Pre- and post-operative radiation therapy has been implicated in vessel damage and impaired wound healing. To date, several reports have quantified the impact of radiation therapy on free flap breast reconstruction. In a cohort study involving 199 patients, Fracol et al. reported an increase in intraoperative vascular complications (14% vs 7%) as well as wound infections (4% vs 0.5%), but no significant difference in postoperative thrombosis, flap loss, mastectomy flap necrosis, hematoma, seroma, fat necrosis or wound healing in irradiated vs non-irradiated sites [3]. Kelly et al. suggested that immediate free flap breast reconstruction can be considered even when post-mastectomy radiation therapy is involved [4]. Mirzakeigi et al. raised concerns of volume loss and fat necrosis, but did not advise against immediate reconstruction [5].

Chemotherapy

While it has not been implicated in flap loss and microvascular impairment, chemotherapy has been known to increase overall complications, such as wound healing and fat necrosis. Timing of chemotherapy does not significantly affect outcome [6].

Smoking

Smoking causes nicotine-induced vasospasm, tissue hypoxia due to elevated carbon monoxide, and increased platelet aggregation leading to hypercoagulability status which can cause flap vascularity impairment and donor site morbidity. Cessation of smoking must occur at least four weeks prior to surgery [7]. Smokers have twice the chance of developing donor site complications after DIEP flap harvesting for breast reconstruction compared to non-smokers [8].

Obesity/BMI

A BMI of over 30 independently increases the overall risk of complications due to prolonged intraoperative time, technical difficulties, and associated comorbidities [6]. Some surgeons advise their patients with a BMI of over 30 to lose weight before breast reconstruction surgery with free flaps [9].

Age

Increasing age is usually associated with other medical comorbidities, implicated in overall poorer surgical outcomes. However, complication rates, including vascular thrombosis following autologous breast reconstruction, do not appear to be significantly higher, leading to the conclusion that age is not an independent risk factor and elderly patients, if fit, can benefit from free flap breast reconstruction [10].

Medical Comorbidities

Diabetes and hypertension impact blood vessels structurally and functionally, leading to a higher possibility of both minor and major complications. Good control of glycemic and blood pressure values is mandatory.

Mastectomy Type

Skin-sparing mastectomies (SSM) and nipple-sparing mastectomies (NSM) present the obvious advantage of retaining the original skin envelope and use the free flap to recreate the volume and shape of the breast with good final overall esthetic results. However, they provide difficult access to the internal mammary vessels, which may lead to unforeseen vascular complications. On the other hand, in the case of both SSM and NSM, an implant-based type of reconstruction is usually preferred. This may sometimes lead to unsatisfactory results and salvage procedures, including reconstruction with autologous tissue, may be required to correct them. In a recently published study, Roostaeian et al. found that capsular contracture was incriminated in 62% of cases of implant removal. Accompanying high rates of radiation therapy also lead to recipient vessel scarring 5.23 times more often. This led them to conclude that major complications are more likely to occur when performing salvage reconstruction. However, the procedure can be safely performed with additional preoperative planning with success rates similar to primary flap-based reconstructions [2].

Prior Abdominal Surgery

Abdominal scars raise the question of viable perforators. Adequate preoperative assessment using computed tomography angiography is most useful. Intraoperative bipedicle perforator flaps or supercharging across scars can allow the usage of large volumes of tissue crossing the midline. However, when in doubt, muscle-sparing TRAM flaps are recommended [11].

Nulliparity

Santanelli et al. recently related nulliparity to several perfusion-related complications (PRC), including fat necrosis and partial flap loss, due to a weaker pattern of perforators, as well as smaller angiosomes. Their recommendation for PRC risk reduction is the use of medial row perforators combined with crystalloid/colloid fluid infusion [12].

PROCEDURE-RELATED RISK FACTORS

VTE Prophylaxis

Venous thromboembolism prophylaxis can be achieved based on accurate risk assessment by physical measures, using compression stockings, intermittent calf compression, and low molecular weight heparin on the day prior to surgery. The use of anticoagulants is a much-debated topic. The recent reduced operative times and complication rates, as well as the employment of perforator flaps, has led to faster mobilization, which has made for fewer combined antithrombotic regimens. Recent studies highlight the risk that multiple antithrombotics increase the hematoma reoperation rate [13].

Anesthetic Management

Anesthetic management should aim to provide a high cardiac output with a systolic blood pressure over 100mmHg, low peripheral vascular resistance, normothermia, excellent analgesia and good urine output, as well as mild hemodilution Hematocrit: 30-35% [14], and ensure good flap perfusion. Optimal intraoperative fluid management should adequately provide all of the above. However, overzealous fluid administration targeting supranormal blood pressure values is not recommended, for it will result in interstitial edema which could compromise blood flow and gas exchange at flap microcirculation levels [13]. On the other hand, fluid under-resuscitation may place the patient at risk for postoperative flap thrombosis [15]. It is also recommended that vasoconstrictive drugs should be avoided.

Timing of Reconstruction

There is a consensus in the literature that immediate reconstruction lowers the overall number of procedures, hospital stays, and medical system costs, thereby providing the patient with the best possible outcome and limiting complication rates. It has been agreed that

reconstruction can be safely performed even when radiotherapy is involved [3-5]. When performing delayed reconstruction, however, we must rely on mastectomy skin flaps which are mostly scarred, contracted and far less compliant, as well as face higher rates of vascular complications [16].

Free Flap Choice

Generally, for free flap breast reconstruction, abdominal-based flaps, such as DIEP and TRAM flaps, are preferred. They have proved to be safe and reliable with well-documented donor site morbidity. Lately, with the progression of microsurgical techniques and postoperative monitoring, DIEP flaps have become the reconstructive method of choice, due to the lower risk of abdominal bulge and hernia when compared with free TRAM flaps [9]. Another abdominal flap which was described for breast reconstruction is the superficial inferior epigastric artery (SIEA) flap. Although less common and mostly reserved for patients who either require a small-sized breast reconstruction or have insufficient abdominal tissue or extensive abdominal scarring, free flaps from the thigh or buttock can also be used. Such flaps are the superior gluteal artery perforator (SGAP), the inferior gluteal artery perforator (IGAP), the fasciocutaneous infragluteal (FCI), the transverse upper gracilis (TUG), and the profunda artery perforator (PAP) flaps. However, fairly recent employment of these flaps has not led to extensive literature documenting complications and outcomes, compared to abdominal-based free flap breast reconstruction.

Intraoperative Management

Technical issues resulting in arterial thrombosis or venous insufficiency have been known to be dominant factors in overall flap failure rates. Most notably, operative time has been proved to be an independent risk factor for flap loss [17]. Operative time can be prolonged for various reasons: combined mastectomy and reconstructive procedures, especially if bilateral, high complexity and technical difficulty in secondary procedures due to extensive scarring impacting both flap harvest and anastomoses, and/or surgeon inexperience with microsurgery. Ways to minimize operative time include having experienced surgeons perform the procedure, two teams working simultaneously, good preoperative mapping of perforators used for safe and expedited flap harvest, use of microvascular anastomotic coupler for venous anastomoses, and the employment of mechanical sutures for subcutaneous wound closure. Ultimately, ischemia time is an important consideration when discussing microvascular complications, as well as a good predictor of flap outcome [17]. Morris et al. studied changes in flaps submitted to 4, 6, and 8h of ischemia and noticed a significant extent of necrosis when compared with controls, leading them to conclude that an ischemia time no longer than 2h is desirable [18]. Prolonged ischemia time has also been associated with microvascular thrombosis and venous congestion in flaps with adequate perforators. It has been hypothesized that metabolic and structural changes occur within blood vessels during ischemia, and reperfusion further traumatizes the anastomosis site [19].

The internal mammary vessels are frequently used as recipient vessels for free flap breast reconstruction. There are studies showing the presence of tachycardia related to internal

mammary vessels anastomoses [20]. Some studies did not find higher complication rates in patients who developed the internal mammary artery tachycardia syndrome [20], but others noticed an increased incidence of complications, such as vascular impairment, venous thrombosis or wound healing related problems [21].

Blood Loss and Transfusions

Anemia and hypovolemia have been known to complicate procedure outcome, patient morbidity and overall recovery. Currently, it is largely accepted that blood transfusions after free flap breast surgery should be administered based on clinical signs of hypovolemia and hemoglobin levels less than 7g/dl. This is most likely to occur in cases of bilateral reconstruction and preoperative anemia. However, blood transfusions are regarded with much skepticism, due to possible involvement of increased microvascular complication rates. The bottom line is that intraoperative efforts must be made to limit blood loss, and adequate perioperative fluid resuscitation must be conducted in order to efficiently avoid hypovolemia.

DEALING WITH COMPLICATIONS

Postoperative Monitoring

The first 72 hours after free flap breast reconstructions are when microvascular complications arise; therefore, close monitoring is mandatory, hourly during the first 24 hours and three-hourly for the next two days. It is well established that early detection and prompt reoperation of perfusion problems can increase flap salvage. Surgeons and their Residents, as well as trained specialized nursing staff, must conduct clinical observation. The color, consistency, temperature and capillary refill of the flap need to be recorded, along with continuous drain monitoring. Recently, objective tools have been used to increase diagnostic accuracy, such as implantable and surface Doppler monitoring, quantitative fluorescence, near-infrared spectrophotometry, visible light spectroscopy, thermography, transcutaneous oxygen measurements, and microanalysis [22]. However, to date no one method has been found to be ideal and various factors may interfere in clinical findings, so that objective measurements must be balanced along with the surgeon's experience when making the decision to take the patient back to the operating room. Such early complications requiring early detection and timely intervention are:

Edema

Postoperative edema that was not present intraoperatively could have many causes, such as an inflammatory byproduct of flap manipulation or a sign of fluid overload, or an early sign of perfusion problems [14, 19]. It must be carefully monitored and interpreted along with other clinical findings, such as flap color, temperature and capillary refill. If prolonged flap edema produces harmful pressure on the anastomosis site leading to microvascular complications, this can be eased by selective removal of sutures and prompt revision of the fluid chart.

Hematoma

Whether it appears from a flap bleeding source or from an anterior thoracic wall bleeding source, being in the microsurgical anastomosis neighborhood, before or after drains removal, makes a hematoma a serious threat for the proper arterial inflow and venous outflow of the flap. Any compression of the flap's pedicle may lead to partial or total loss of the flap. There are studies highlighting surgical management of a hematoma as high as 13%, not only to remove the hematoma, but also to correct the secondary complications: venous congestion or flap thrombosis [13].

Hematoma in the reconstructed breast is not an often seen complication, usually ranging from 2.89-4.4% [9, 23, 24]. A higher incidence of breast hematoma was encountered after double free flap breast reconstruction [24].

Microvascular Complications

Microvascular complications are probably the worst and the most frightening complications for the Plastic Surgeon. These kinds of complications are the easiest way to lose a flap, and a high percentage are due to the surgeon's microsurgical skills. When referring to microvascular complications, we include arterial and venous thrombosis and also venous congestion.

Tamoxifen, a selective estrogen-receptor modulator frequently used in breast cancer patients, was debated for a long time regarding its possible pro-thrombotic effect on free flap breast reconstruction. Some authors considered tamoxifen to be a thrombotic risk factor, others considered that the prothrombotic effect would be minimized by stopping the tamoxifen two weeks prior to free flap breast reconstruction surgery [25], and others did not consider it as affecting in any way the thrombotic complications of the flap [26]. We prefer to reduce as much as possible any thrombotic risks, so we tell our patients to withhold the tamoxifen for two weeks before free flap breast reconstruction surgery.

Arterial Thrombosis

Clinical aspects of arterial thrombosis include a pale and cold flap, absent capillary refill, or absent Doppler signal at the perforator site. Arterial thrombosis may appear intraoperatively, immediate or late postoperatively. No matter when it happens, it is an emergency and needs re-exploration of the anastomosis in an attempt to save the flap. If the flap cannot be saved after re-exploration of the anastomosis, it needs to be removed.

It is also known that intraoperative microanastomotic technical problems are associated with higher delayed arterial thrombosis [27]. Arterial thrombosis can lead to partial or even total flap loss. In a study on 169 free flap breast reconstruction with DIEP flaps (125 cases) and SIEA (44 cases), Coroneos et al. concluded that higher rates of arterial thrombosis were met in SIEA flap breast reconstruction compared with DIEP flap [28]. Lower SIEA free flap success rates were found in other studies, too, compared with DIEP free flaps, with total necrosis of the flaps as high as 12% [29].

Venous Congestion

Venous congestion occurs intraoperatively in 3.3% of DIEP flaps and 1% of TRAM flaps [30]. Lower incidences are related to secondary venous anastomosis (frequently superficial inferior epigastric vein to cephalic vein) [29]. During abdominal-based flap dissection, the

superficial venous system is interrupted, and it is up to the deep venous system to provide adequate drainage. Venous insufficiency is not a routine issue on the ipsilateral side, but problems may arise concerning the contralateral side because of restricted drainage across the midline [23]. If noticed intraoperatively, venous congestion must be addressed. Solutions vary from simple to complex. In the case of DIEP flaps, most used is the second DIE vena comitante which can be anastomosed to the second internal mammary vein. It is not advisable to use the distal stump of the IM vein because it may have valves. If this does not provide sufficient relief, the superficial inferior epigastric vein (SIEV) usually preserved during flap dissection can either be anastomosed to the main pedicle or to the cephalic, circumflex scapular or toracodorsal vein, according to the surgeon's preference. If neither vein can be used, the contralateral DIE venous system or the cephalic end of the ipsilateral DIE vein can be considered as options. If no additional procedures offer sufficient relief, flap reduction must be considered [22].

Authors have reported a reduction of venous congestion incidence by primarily performing two venous anastomoses; however, this has not become routine practice [31]. If no venous congestion is noted intraoperatively but it occurs postoperatively, it requires urgent exploration of the venous anastomosis and, if viable, performing a secondary anastomosis to relieve outflow is advised. In selected cases of mild venous congestion, conservative measures may apply, such as leach therapy or the topical use of nitroglycerine [32].

Venous Thrombosis

Venous thrombosis occurs more often than arterial thrombosis with reported rates as high as 10% [33] and has higher salvage rates [34]. Clinical findings are similar to venous congestion: edema, bluish discoloration, accelerated capillary refill. Urgent exploration of the venous anastomoses must be conducted. Early detection has been reported with the use of an implantable Doppler probe and venous flow coupler [35].

Infection

As in any other infection, the clinical signs are edema, erythema and local warmth, induration, possibly the presence of pus. Treatment ranges from oral antibiotics to intravenous antibiotics, depending on the severity of the infection. Sometimes surgical debridement might be necessary. Fortunately, low incidences of flap infection are encountered [23]. Compared with bilateral free flap breast reconstruction, the incidence of infections seems to be higher in unilateral free flap breast reconstruction [24].

Wound Dehiscence

Wound dehiscence is secondary to local infection or marginal necrosis, with or without partial flap loss. Surgical debridement is usually necessary, followed by secondary wound closure. In small wound dehiscence, conservative management might be sufficient for a good result. In case of wound dehiscence secondary to local infection, antibiotic treatment must be added.

PERFUSION-RELATED COMPLICATIONS

Fat Necrosis

Fat necrosis is a well-established perfusion-related complication that has been known to occur in up to 19.1% of cases [36]. There is general consensus that, if it occurs, fat necrosis should be managed conservatively, and any contour defects can be addressed at a later date by using fat grafting. Preventing such complications, however, has been the focus of much research. Recently, Lee et al. suggested that preoperative volumetric planning using computerized tomographic angiography can aid in decreasing perfusion-related complications [36].

Flap Failure

Current flap failure rates reported by specialized centers range from 0.5% to 2.5% [9, 23], with partial flap failure rates higher than total flap failure. Leading causes are venous congestion and thrombosis [9, 23, 37]. Flap failure is a major setback in patient care with a negative impact on the patient's psychological status. Therefore, adequate counseling and support must be provided. Also, it adds to overall costs, increases hospital stay, and raises the need for a further procedure. For all these reasons, strenuous efforts must be made to identify the cause of flap failure, as such cases can provide valuable lessons. The questions are: was it failure to plan, failure to execute, failure to monitor, or the association of multiple risk factors.

Accurately identifying the cause can improve future conduct and influence further reconstructive decisions. For instance, cases of essential thrombocytosis or thrombophilia [23, 38] have been diagnosed post flap failure and this has guided the decision of further performing an implant-based breast reconstruction instead of another free flap. Both partial and total flap loss must be managed with early debridement in order to prevent infection and salvage as much viable tissue as possible. In the case of primary reconstruction post skin-sparing mastectomy, skin flaps can provide sufficient wound coverage for primary closure and allow for delayed reconstruction. Other options would be to consider another free flap from the thigh or buttock and attempt a primary reconstruction, or to perform an implant-based reconstruction with a *latissimus dorsi* (LD) flap. On the other hand, for delayed reconstructions in case of flap failure, there is not enough skin to primarily close the wound after debridement and, in order to avoid using a skin graft, another free flap reconstruction should be considered, as well as an LD flap.

Donor Site Complications

These generally include seroma, hematoma formation, infection, delayed wound healing and scarring. More specific to the use of abdominal-based free flaps for breast reconstruction are mesh complications, hernia and abdominal bulge. Morbidity associated with thigh and buttock based flaps is related to long-term contour defects that may represent a challenge in

correcting. In this regard, least impairing, in our opinion, is the FCI flap when small to medium volumes are employed for breast reconstruction in patients with insufficient abdominal tissue, leading to high levels of patient satisfaction.

Recently, Mirzabeigi et al. reviewed an under-reported complication of abdominal-based free flaps: chronic wound healing. In a study reviewing 1218 patients, they found 13.7% cases of delayed wound healing, which was related to abdominal wall sequelae, such as hernia. Risk factors for delayed wound healing at 30 days leading to chronic abdominal wounds were found to be obesity, smoking, bilateral reconstruction, preoperative chemotherapy, and the use of abdominal mesh. Their recommendation in dealing with this complication was to perform early postoperative debridement and primary wound closure in order to improve patient outcomes [39].

Scarring

Body image is very important when talking about self-esteem. Scars are part of a patient's life after any surgery. When talking about scars after breast reconstruction, we need to deal with scars at the place of reconstruction and at the donor site. Studies show that patients usually prefer donor site scars for breast reconstruction in a body area that they do not see [40, 41]. For example, the LD flap scar was preferred over the DIEP flap scar [41]; even better, the SGAP scar was preferred over the DIEP flap scar [40].

On the other hand, when talking about post breast reconstruction scars, more than half the patients prefer the scar after immediate DIEP flap reconstruction, compared with LD, expander/implant or delayed DIEP flap reconstruction [40].

Like any other scars, these scars might transform into hypertrophic or, even worse, keloid scars. The methods of treatment for these pathologic scars vary from surgical treatment to intralesional corticosteroid injections, laser therapy, silicone sheet, radiotherapy or a combination of these methods.

Other Complications

Other rare complications have been encountered when dealing with free flap breast reconstruction methods. Internal mammary artery tachycardia syndrome was described in those patients in whom the anastomosis of the flap's pedicle was performed at the internal mammary vessels. This tachycardia syndrome was more frequent in cases of anastomosis to the internal mammary vessels compared to the thoracodorsal vessels (58% vs 23%) [20]. A case of cardiac tamponade followed by cardiac arrest was reported, secondary to left internal mammary vessels isolation for microsurgical anastomosis for breast reconstruction [42].

CONCLUSION

When an acute thrombotic event is identified early in the first few hours after surgery, we are in favor of trying a salvage procedure. However, when late onset of thrombosis is

identified or unrecognized, in our experience all efforts at salvage are in vain and only put the patient under stress.

Chapter 179

MANAGING COMPLICATIONS IN FREE-FLAP BREAST RECONSTRUCTION

Gordon K. Lee¹, Jarom N. Gilstrap¹ and Jennifer E. Cheesborough²

¹Plastic Surgery at Stanford University, Stanford, CA, US

²Northwestern University, Evanston, IL, US

ABSTRACT

Breast cancer treatment remains on the forefront of healthcare in the United States, affecting nearly one in eight women in their lifetime [1]. With increasing awareness and policy changes, such as the Women's Health and Cancer Rights Act of 1998 [2], breast reconstruction rates have continuously climbed over the last two decades, a nearly 35% increase since 2000 [3]. Breast reconstruction with free autologous tissue, gaining widespread popularity in the 1990's, can provide a natural, aesthetic breast shape while avoiding many of the pitfalls associated with implant-based reconstruction [4-6]. The number of available donor sites and flap types has also increased dramatically in recent years. Today, autologous tissue constitutes close to 20% of breast reconstruction [7].

CONSIDERATIONS FOR FREE-FLAP RECONSTRUCTION

There is no one "best" method for breast reconstruction, as evidenced by the variety of methods seen in practice today. However, there may be a "perfect" method for an individual patient. Appreciating several factors when deciding on the method of reconstruction is critical. Among these are:

- *Patient factors*- obesity and other comorbid conditions, bleeding disorders, tobacco use, available donor tissue, lifestyle, previous surgery, recreational and occupational activities, preference, and need for adjuvant therapy.
- *Surgeon/Facility factors*- Surgeon training/background and comfort with microsurgical practices, availability of operating room equipment, personnel and adequate post-operative monitoring.

- *Mastectomy and incision type-* Traditional modified radical mastectomy, skin-sparing mastectomy, nipple-sparing mastectomy (including incision for approach) and surgical technique of extirpative surgeon.

TIMING

The timing of reconstruction plays a role in outcomes. Immediate autologous reconstruction is usually reserved for patients with early stage cancer who do not require post-operative radiation. Several studies have demonstrated the benefits of reconstruction for the breast cancer patient's body image and quality of life [8, 9]. Delayed reconstruction is usually recommended for patients who will require radiation, although this remains controversial. Delayed reconstruction is also indicated for those patients who underwent mastectomy at a center that does not have a plastic surgeon available for immediate reconstruction, those who have lost their implant-based reconstruction due to infection, and for patients who elected to postpone their reconstruction in order to begin adjuvant therapy. Compared with the aesthetic results obtained from immediate reconstructions in which the majority of the breast skin is maintained, delayed reconstructions yield modest results [10-12]. More recently, a delayed-immediate approach has been developed for individuals with intermediate disease whose radiotherapy needs are undetermined prior to mastectomy and lymph node assessment [13].

RISK FACTORS

Several factors have been linked to increased risk of complication in free tissue-based reconstruction. Factors include: Smoking [14], obesity [15-18], diabetes [19], breast size, bleeding disorders, and previous abdominal surgery [20, 21].

COMPLICATIONS AND MANAGEMENT

Understanding the diagnosis and management options of free flap complications is vital to patient care. Complications will be divided into three categories and discussed in depth:

Complications Related to Reconstructed Breast:

Anastomotic failure, total free flap loss, partial flap loss [22-24], fat necrosis [25], mastectomy flap necrosis, hematoma, seroma, infection, pneumothorax

Complications Related to Donor Site:

Hematoma, seroma, delayed wound healing, dehiscence, abdominal skin flap necrosis, numbness/altered sensation, abdominal wall weakness, hernia [26, 27]

Complications Related to Prolonged Surgical Time:

Myocardial infarction, cerebrovascular accident, venous thromboembolism, pressure ulcers, compressive neuropathies

COMPLICATIONS RELATED TO THE RECONSTRUCTED BREAST

Anastomotic Failure

Creation of a patent microsurgical anastomosis is a skill requiring practice and refinement, however, even the most experienced microsurgeon will occasionally experience problems with a vessel requiring revision. A published failure rate of 3-5% means that if one does enough free flaps, one will eventually fail (Figure 1).

Figure 1. Total flap loss.

Diagnosis

Anastomotic failure can be either arterial or venous in origin and can be subdivided into complete occlusion or insufficient flow. Arterial occlusion is diagnosed clinically as a pale, cool flap with poor turgor (Figure 2), whereas a venous problem will manifest as a swollen, purple flap with rapid capillary refill and brisk, dark bleeding (Figure 3). Timing is key and early recognition of vascular compromise is vital to flap salvage (Figures 4 and 5). These issues can be identified in the operating room or may not be apparent until the post-operative period. Thrombosis typically occurs within the first 48 hours in 80% of patients. Monitoring the free flap during the postoperative phase is critical to ensuring flap survival in the event of anastomotic failure. When recognized early and managed promptly, compromised flaps have a 75% salvage rate when taken back to the operating room. Thus, all personnel responsible for flap monitoring must be knowledgeable about the appearance and evaluation of the healthy and compromised flap.

Figure 2. Arterial insufficiency presents as a pale flap with poor turgor and slow capillary refill. Be cognizant of the donor site skin tone as well when examining the flap.

Figure 3. Venous congestion presents as a purple, swollen flap with brisk capillary refill and dark red bleeding.

Figure 4. Venous congestion requires emergent return to the operating room for exploration. If intervened upon early in the course, the flap is potentially salvageable.

Figure 5. Later in the course the flap will demarcate as partial or complete flap loss.

The most important variable to flap salvage is early identification and early action. Studies have demonstrated that venous thrombosis alone is more common than either arterial or combined arterial and venous thrombosis [24]. While physical examination is the gold standard, many methods and technologies are available to aid in the diagnosis of anastomotic failure. Intraoperatively, one can look for visible pulse, Doppler signal, Flicker test (Figure 6), milking the vessel, laser flowmetry, indocyanine green angiography (Figure 7), etc. Similar modalities for flap monitoring are available in the post-operative period. In fact, a healthy debate continues regarding modalities of post-operative monitoring with such devices as the implantable doppler, Vioptix, etc. (Figure 8). However, clinical examination remains the gold standard.

Figure 6A. This test is somewhat traumatic. Occlude the vessel with forceps distal to the anastomosis (A). Place another forceps just distal to the first (B). Milk the vessel for several millimeters away from the anastomosis (C). Occlude the emptied vessel, and release the proximal forceps.

Figure 6B. You should see rapid filling from proximal to distal (D). If you don't see rapid filling, then there is anastomotic failure (E).

Figure 7. ICG angiography- patent couple venous anastomosis (red arrow). The patent arterial anastomosis can also be seen at the bottom of the photograph.

Figure 8. Vioptix System relies on tissue oxygen perfusion and is available for monitoring through smart devices.

Management

Re-operative exploration of the compromised or potentially compromised flap is required. Removing sutures to relieve pressure on the flap caused by skin closure can be performed, but even in the case of clinical improvement after this maneuver, exploration is still essential. One should visualize the anastomosis and perform exercises to determine where the problem may lie. Technical errors (back wall stitch, narrowing, intimal damage, twisting, kinking of the vessels) are the most common reasons for anastomotic failure (Diagram 1). These are solved by takedown and revision of the problematic anastomosis or

anastomoses. Thrombectomy, heparin flush and tissue plasminogen activator (tPA) flush may also be useful, depending on the situation encountered. One should always perform an examination of the lumen and remove any damaged portions of the vessel. A step-wise approach to evaluation of the vessels is outlined below.

1. Look for kinking of the vessels: Kinking can often be identified on re-exploration, however the vessel may kink only when the flap is inset. Vessel 'lie' should be meticulously observed. Sometimes a small stay stitch will help prevent kinking or twisting. Occasionally, the vessels need to be shortened due to excess length of one or both of the vessels (usually the artery is longer). A vessel that is too long may have folded in the excess portions, requiring an adjustment in placement of the vessel or flap inset. A vessel that is too short may kink at an anchor point. Oftentimes, further dissection of the recipient vessel or anchor point is all that is required. Occasionally an interposition vein graft is required. Kinking may also be prevented by using gel-foam or local tissue to pad a gentle curve of the vessels.
2. Look for twisting of the vessels: A vessel may be twisted unknowingly prior to anastomosis and go unnoticed while the vessel is flaccid. When the vessel clamps are removed and flow is re-established, this problem may become more apparent. A twisted vessel typically requires revision of the anastomosis. Marking the orientation of the donor and recipient vessels prior to anastomosis may aid in identifying and preventing any twisting.
3. Look for excess vessel traction. Stretch should not be an issue, as an anastomosis should never be performed under tension. However, shifting of the flap on inset can cause tension on the vessels. Undue tension can cause fracture of the endothelial lining and ultimately vessel thrombosis. If tension is the culprit for flap compromise, the anastomosis may need to be taken-down, examined for intimal damage and revised. An interposition vein graft can be used to achieve additional pedicle length necessary for proper flap inset. Adjusting the flap orientation, further vessel dissection to achieve additional pedicle length or placement of an interposition vein graft will help to reduce tension on the vascular pedicle.
4. Look for any areas of vasospasm: Vasospasm is the subject of much debate. It can be caused by intrinsic factors triggered by rigorous dissection and vessel handling. Extrinsic factors may also be present, such as administration of sympathomimetics. The best approach is warming, gentle vessel dilation, sympathectomy by adventitial stripping and use of vasodilatory agents. Multiple classes of agents have been studied and used for this effect, including phosphodiesterase inhibitors (papavarine, phentophylline, amrinone), local anesthetics (lidocaine), calcium channel blockers (nicardipine, verapamil, nifedipine, magnesium sulfate), direct vasodilators (sodium nitroprusside, prostaglandin E1, nitroglycerine, hydralazine) and alpha antagonists (phentolamine, chlorpromazine) [28]. Recent animal studies suggest that topical magnesium sulfate may be most effective in its spasmolytic effects [29].
5. Look for signs of external compression. Hematoma is the most common reason for external compression compromising flap blood flow and requires immediate evacuation (Figure 9). Surrounding pressure must be prevented (hemostasis) and often times, the anastomosis will require revision. Additionally, 'leaking' anastomoses may trigger intraluminal activation of the clotting cascade, exacerbating

the problem. One must be aware of the vessel lie in regards to adjacent structures such as the ribs and pectoralis major when utilizing the internal mammary vessels as recipients. A tight overlying skin closure may also provide external compression and flap compromise. At the time of initial closure/flap inset, some amount of flap swelling should be expected and planned for. Finally, the surgeon must be aware of other types of sabotage in the way of external compression (abdominal binders, surgical bras, heating pads, patient lying on the flap, etc.). The weight of the flap itself is not typically a site of external compression.

Figure 9. Large, expanding hematoma. Note as well the congested appearance of the flap. Often times, a hematoma may cause compression of the venous drainage and lead to congestion of the flap.

If an early thrombus is present, one must address the underlying issues as illustrated above. Unexplained thrombosis is an ominous sign. If no other factors can be identified, one can only redo the anastomosis and hope. The “No Reflow Phenomenon” [30-32] is related to tissue reperfusion injury at the level of the capillaries and often times is not a salvageable event.

Hypercoagulable states are the subject of much debate. Patients with cancer are often hypercoagulable at baseline. Additionally patients may be on medications that increase risk of venous thromboembolism (tamoxifen, oral contraceptives, etc.). Still other patients may have a native hypercoagulable state due to Factor V Leiden or lupus anticoagulant, for example. Others clues to hypercoagulability (unexplained miscarriages, family or personal history of VTE) should be elicited pre-operatively.

Patent anastomosis, but clinical flow insufficiency, may become apparent. More often this is venous in origin leading to a turgid, hyperemic flap. A patent anastomosis but venous insufficiency should be super-charged whenever possible. In the case of a TRAM flap, use of the SIEV coupled to the retrograde IMV, thoracodorsal or thoracoacromial system can provide a useful bailout (Figure 10). Arterial insufficiency is harder to diagnose and often times only manifests weeks later in the form of fat necrosis. Debate remains regarding actual flow rates to flap size/volume.

Figure 10. This flap has been raised on the deep inferior epigastric system, however, note the congested appearance. This flap required supercharging with the superficial inferior epigastric vein.

A clot indicates activation of the coagulation cascade. For this purpose, the surgeon may need to perform a thrombectomy (typically using a size 2 or 3 Fogarty catheter) and heparinize the flap, in addition to revising the anastomosis. In late thromboses, thrombolytic therapy (tPA, streptokinase, urokinase, etc.) may also be considered. If used, thrombolytics should be restricted to flow through the flap by allowing drainage through an unused venous outflow tract, rather than systemic administration.

When a free flap ‘goes down,’ and salvage is unsuccessful, there are four options:

1. Perform a second free flap, if the patient is medically stable.
2. Perform a pedicled flap: May be possible to perform a pedicled latissimus flap or TRAM flap, under the right circumstances.
3. Implant-based reconstruction: Placement of tissue expanders, if possible
4. Delayed reconstruction: Close incisions.

It is imperative that informed consent includes the possibility flap failure and secondary options and that this be discussed with the patient pre-operatively.

Total Free Flap Loss

Diagnosis

Total flap loss represents vascular compromise (Figure 11). This may be an unrecognized flow problem at the level pedicle or it may be at the capillary level, as in the case of the no-reflow phenomenon. The problem will often be readily apparent in the first several postoperative days, but may present later.

Figure 11. Total flap loss.

Management

Integral to the treatment of flap loss is identification of etiology for failure. The only thing worse than a total flap loss is a second total flap loss. Care should include timely debridement and immediate or delayed reconstruction. The decision for reconstruction should again be approached with the patient and appropriate options discussed. Discussion may include consideration of a second free flap or placement of a tissue expander with or without a pedicled latissimus dorsi flap for additional soft tissue coverage.

Partial Flap Loss

Diagnosis

Partial flap loss may be very apparent with areas of demarcated skin or may be more insidious in nature, in the form of fat necrosis (Figure 12 and 13). Both of these entities represent insufficient flow. This is different than mastectomy flap necrosis, which is principally dependent on patient factors and technique of the extirpative surgeon. Partial flap loss may be due to non-occlusive clots at the level of the anastomosis, emboli originating at the anastomosis, insufficient flow volume to flap size (zone 4 necrosis, for example) or any other insult to the intrinsic blood flow of the flap (such as prolonged ischemia time leading to reperfusion injury). In many cases, as with any anastomosis failure, the primary cause is technical error. In regard to flow size to flap volume, the advent of free abdominal tissue transfer based on the deep inferior epigastric artery has improved outcomes. While technically a Mathes and Nahai type III muscle [33], the rectus abdominis muscle does show a dominance of the inferior epigastric artery, leading to much less distal flap loss and fat necrosis than the superior epigastric-based pedicled TRAM. However, some degree of flow discrepancy may occur and the answer to specific flap mass to flow rate has yet to be

elucidated. At this point, flap size to pedicle size and flow relies on clinical judgment and acumen of the operating surgeon and a sound understanding of Taylor's angiosome theory [34]. The evolution of intraoperative indocyanine green angiography has, minimized flap loss when utilized. Evidence shows that on-table ICG angiography allows the surgeon to preemptively debride portions of the flap that show insufficient flow, thus precluding any need for later debridement [35-39].

Figure 12. Partial flap necrosis.

Figure 13. Fat necrosis.

Management

The management of partial flap loss is an evolving field. Management of partial flap loss is primarily to allow the flap to demarcate, debride necrotic portions and revise as necessary (Figure 14). Adjunct techniques to supplement for the loss of tissue would include fat grafting, local tissue rearrangement, and/or prosthetic implants. It is not absolutely necessary to remove every bit of fat necrosis, rather only that which is palpable and clinically relevant.

Figure 14A. Spotty areas of superficial skin necrosis.

Figure 14B. These areas are debrided and allowed to heal by secondary intention.

Figure 14C. Although additional scarring is present, this patient went on to have a good result with excellent symmetry and breast shape.

Fat Necrosis

Diagnosis

Fat necrosis is caused by saponification of dead or damaged fat tissue after trauma or ischemia to the breast (Figure 13). At a microscopic level, the initial change is disruption of fat cells where vacuoles with the remnants of necrotic fat cells are formed. Lipid-laden macrophages, multinucleated giant cells, and acute inflammatory cells then engulf them. Fibrosis develops during the reparative phase peripherally enclosing an area of necrotic fat and cellular debris. Eventually, fibrosis may replace the area of degenerated fat with a scar, or loculated and degenerated fat may persist for years within the scar tissue. Clinically, fat necrosis presents as a firm lump or lumps and can be associated with pain or discomfort and erythema. It can be seen in the breast after needle biopsy, lumpectomy, radiotherapy or other trauma. In the setting of breast reconstruction, fat necrosis may represent insufficient flow to portions of the transferred flap or tissue trauma.

Management

While a new mass in the reconstructed breast may be distressing to the patient, in a post-mastectomy reconstruction, this typically does not represent cancer recurrence. Certainly, in a patient who had partial breast removal (lumpectomy), a new mass warrants a complete cancer work up. Mammography of fat necrosis will often reveal stippled, curvilinear calcifications within the periphery creating the appearance of lucent “bubbles,” with low-density centers. Ultrasound typically reveals a hypoechoic mass with well-defined nodular margins. Management requires patient reassurance and excision/revision versus non-surgical management depending on symptomology and patient wishes. Adjunct techniques to supplement for the loss of volume would include fat grafting, local tissue rearrangement, and/or prosthetic implants. As noted above, only clinically significant fat necrosis need be removed.

Figure 15. Mastectomy flap necrosis.

Mastectomy Flap Necrosis

Diagnosis

Mastectomy flap necrosis is damaged, poorly perfused breast skin, which presents as an area of demarcating necrosis within the first days to weeks after mastectomy (Figure 15). This

is due to patient factors, including smoking/nicotine use, obesity, diabetes, previous breast size and radiation. Mastectomy flap necrosis is also related to surgical technique of the extirpative surgeon, such as intraoperative tissue handling and plane of dissection.

Management

The management of mastectomy flap necrosis is evolving with the use of ICG angiography, allowing reconstructive surgeons to preemptively excise devascularized skin at the time of initial reconstruction if tumescent is not utilized during mastectomy. Another strategy to address this vexing issue is to bury the immediate free flap without performing de-epithelialization and plan to bring the patient back several days later, excise demarcated breast skin, perform de-epithelialization and inset the flap [40]. This technique, however, does require a return trip to the operating room. At this time, the most commonly employed strategy is to try to identify any questionable areas of breast skin intraoperatively and preemptively debride. For postoperative necrosis, recommendations include debridement and revision (Figure 16).

(a)

(b)

Figure 16A-E. (Continued).

Figure 16A-E. Mastectomy flap necrosis, requiring serial debridement, wound care and ventral skin grafting.

Hematoma

Diagnosis

As with all operations, hematoma formation is a risk of free flap breast reconstruction. A hematoma will typically present as an expanding mass and overlying ecchymosis (Figure 17). However, in the case of a hematoma in free flap breast reconstruction, there is added concern for flap compromise due to pressure on the pedicle. Evidence shows that hematomas are not prevented by drain placement.

Management

Hematoma after breast reconstruction mandates prompt diagnosis and evacuation if there is clinical compromise to the flap. Re-exploration should be performed in the operating room in order to thoroughly examine the anastomosis (especially the venous anastomosis) and ensure hemostasis. Hemoglobin should be checked regularly and be kept above 10g/dL and hypovolemia treated with fluid and blood products, rather than sympathomimetics. There is mounting evidence in the head and neck literature demonstrating that the perivascular

sympathectomy performed with vessel dissection blunts the effect of sympathomimetic medications, however this has not been studied in the breast reconstruction literature and should be avoided, if possible.

Figure 17. Hematoma.

Seroma

Diagnosis

Seromas may present both in the donor site as well as the reconstructed breast site. They typically present later in the clinical course (Figure 18). They typically do not cause external compression and vascular compromise.

Figure 18. Right sided breast seroma.

Management

Seromas may be treated symptomatically with aspiration under sterile conditions and/or closed suction drainage. Occasionally, a seroma may be refractory to serial aspiration and require placement of a drain or use of sclerosing therapy. Sclerosing agents should be avoided in the area of the vascular anastomosis.

Infection

Diagnosis

Infection, as with all surgical procedures, represents a real risk especially if there is prolonged surgical time or the patient experiences intraoperative hypothermia (Figure 19). Complicating the diagnosis, typical signs of infection (such as erythema) can occasionally be mistaken or masked as vascular compromise. For this reason, the operating surgeon should be liberal in obtaining cultures, particularly at the time of re-exploration or revision. As an added risk in the free flap patient, infection can be a trigger for vessel thrombosis. Infection presents as erythema, pain, warmth, purulent drainage, and can cause breast skin or flap necrosis.

Figure 19. Superficial cellulitis.

Management

Evidence regarding prevention of surgical site infection follows the 2006 Surgical Care Improvement Project (SCIP) protocol. Patients should receive preoperative antibiotics. Antibiotics should be re-dosed appropriately intraoperatively and attention should be given to maintain normal body temperature. Abscesses or deep-seated infections should be treated with drainage, debridement and appropriate antibiotic coverage. There is no evidence for prophylactic antibiotics beyond the immediate perioperative period.

Pneumothorax

Diagnosis

Pneumothorax is a possible complication of rib resection and exposure of the internal memory vessels. Classically, this presents at the time of occurrence as a visible rent in the

parietal pleura and audible sucking sound. Intraoperatively, irrigation fluid can be introduced into the trough created by rib resection and if bubbles are observed rising through the fluid, it is likely the pleura has been violated. Rarely, pneumothorax can present in the postoperative period with hypoxia, tachycardia and shortness of breath. Workup should include chest and abdominal x-rays.

Management

Optimally, pneumothorax is identified at the time of occurrence. This typically does not require treatment unless a lung injury occurs. The patient is receiving positive pressure ventilation, and use of a closed suction subcutaneous drain in the breast reconstruction pocket is sufficient to remove any residual air and prevent subcutaneous emphysema. Typically, there is no need for placement of a chest tube. A post-operative chest radiograph can be obtained if there is concern for pleural violation. There is no evidence supporting routine postoperative chest radiograph. Should the patient present with a post-operative symptomatic pneumothorax, a chest tube should be placed.

Poor Cosmetic Outcome

Diagnosis

Modern breast reconstruction has in many ways ‘raised the bar’ in terms of patient expectations of cosmetic outcome. More and more patients expect a rapid return to ‘normal’ life with a reconstructed breast indistinguishable from or better than their pre-operative status. Critical to management of cosmetic concerns is establishing patient expectations early with regards to their final outcome. A suboptimal cosmetic outcome may be due to several factors including effacement of the inframammary fold, asymmetry, contour irregularities, skin tone differences (between donor skin and breast skin), fat necrosis, etc.

Management

Cosmetic revision should be addressed primarily with expectant management as much as possible, as the patient will experience a certain amount of settling in the year after surgery. However, revisional surgery including liposuction, fat grafting, etc., may safely be performed six weeks after the initial reconstruction. Further discussion regarding cosmetic revision is beyond the scope of this chapter.

COMPLICATIONS RELATED TO THE DONOR SITE

Abdominally-Based (Free TRAM, ms-TRAM, DIEP, SIEA)

Hernia/Abdominal Wall Weakness

Diagnosis

In an effort to minimize dysfunction of the abdominal wall, advancements have been made in techniques to decrease rectus muscle and fascia injury, leading to advocacy for the

DIEP flap [41-43]. In 2006, Garvey, et al., demonstrated a 16% hernia rate in pedicled TRAM versus 1% in the DIEP cohort [44]. Several subsequent studies demonstrated conflicting or equivocal results [45, 46]. More recently, in a large multi-center database search including 8246 patient, Fischer et al., demonstrated surgically-repaired abdominal wall hernias in 7% of pedicled TRAM patients, 5.7% in free TRAM patients and 1.8% in DIEP patients (Figure 20 and 21) [27]. Abdominal wall weakness or hernia may be subclinical or asymptomatic and go unnoticed unless found incidentally by CT scan for other reasons. However, symptomatic or clinically apparent abdominal bulges or hernias should be addressed surgically. The primary advantage of the SIEA flap over those based upon the deep inferior epigastric or superior epigastric system is the lack of penetration of the abdominal fascia and muscle thus eliminating the risk of subsequent abdominal wall weakness/bulge or hernia.

Figure 20. Abdominal bulge.

Figure 21. Abdominal bulge.

Management

The average time to hernia repair after abdominally-based breast reconstruction is approximately 1 year [27]. Treatment involves exposure of the rectus fascia with primary closure and mesh reinforcement. The authors recommend that at the time of initial reconstruction, the fascia and abdominal musculature be carefully evaluated as it may be advised to place mesh prophylactically to prevent post-operative hernias and bulges.

*Hematoma***Diagnosis**

Abdominal hematomas are experienced in a small percentage of the patients undergoing abdominal-based breast reconstruction. They present as expanding masses and ecchymosis as well as increased sanguinous drain output.

Management

Hematomas should be treated with re-exploration to remove the hematoma, irrigate and obtain hemostasis,

*Seroma***Diagnosis**

Seromas more commonly present in the abdominal donor site, rather than at the site of breast reconstruction. They will typically present several weeks to months after the time of initial surgery. Abdominal seromas are similar to those occurring in cosmetic abdominoplasty and present as fullness which may or may not be ballotable and occasionally uncomfortable. Erythema is a sign of underlying infection.

Management

Decreased seroma formation has been linked with placement of intermittent quilting sutures [47, 48]. Seromas may safely be treated when symptomatic with aspiration under sterile conditions and/or closed suction drainage. Occasionally, a seroma may be refractory to serial aspiration and require use of drains, sclerosing agents or even surgical removal of the seroma cavity.

*Wound Dehiscence***Diagnosis**

Wound dehiscence or abdominal flap necrosis may occur at the site of abdominal closure and typically occurs centrally, at the site of highest tension (Figure 22 and 23). This is most often due to ischemia from tight closure and will appear pale intraoperatively, followed by a progression to local purpura and finally frank necrosis of the skin and underlying fat with associated wound failure. The risk of this complication is increased when there is a T-junction as may occur at the site of the transposed umbilicus. This may be very discouraging to the patient, who has had an otherwise successful operation.

Management

Optimal management is avoidance of high-tension closure. Occasionally, paucity of abdominal tissue on an otherwise small-framed patient may dictate a tighter closure than desired. Progressive tension sutures can be used and the wound may be temporarily supported with an incisional negative pressure device (wound vac). The patient should be advised to remain in a flexed position at the waist for several days to weeks to minimize tension on the abdominal closure. Should the patient develop an open wound despite all precautions, the wound should be managed conservatively with moist dressings, debridement as indicated, and healing by secondary intention. A wound vac may also speed wound closure.

Figure 22. Abdominal wound failure. Notice the central location, representing the area of most distal perfusion as well as the area of highest tension.

Figure 23. Abdominal wound failure.

Bowel Perforation/Enterocutaneous Fistula**Diagnosis**

While no portion of the harvest of an abdominal flap for breast reconstruction should proceed to the intra-abdominal cavity, there is a small risk of bowel perforation with harvest of abdominally-based flaps based upon the deep inferior epigastric system. The patient will present postoperatively with inability to tolerate oral intake and nausea/vomiting. Abdominal radiographs should be obtained and will show subphrenic air and air-fluid levels.

Management

The patient will require exploratory laparotomy with general surgery to identify and repair the enterotomy.

*Numbness/Altered Sensation***Diagnosis**

Peri-incisional and peri- and infra-umbilical numbness is a common occurrence following abdominal-based breast reconstruction. This altered sensation is due to transection of the local cutaneous nerves or a cutaneous neuropraxia from retraction. Patients may also experience a burning or tingling sensation in a similar distribution associated with nerve regeneration. Occasionally patients may complain of pain or burning in the thigh or groin due to injury of the lateral femoral cutaneous nerve or the ilioinguinal nerve, similar to that seen in abdominoplasty.

Management

Local changes in sensation; numbness, burning, and tingling may be treated expectantly, with return of normal sensation in six months to one year. Patients may be instructed in desensitization techniques to help in the meantime. If the lateral femoral cutaneous nerve or ilioinguinal nerve is injured or tethered by suture, it may require operative intervention depending upon the severity and persistence of symptoms.

Thigh-Based Flaps, Such as Gracilis Flaps*Lymphedema***Diagnosis/Management**

While uncommon, lymphedema is a potential and devastating complication in patients undergoing a transversely-oriented upper gracilis (TUG) flap. Care should be taken to avoid carrying the dissection too deeply/anteriorly over the femoral triangle. The best treatment is avoidance. A thorough discussion of treatment modalities for lower extremity lymphedema is beyond the scope of this book.

*Seroma***Diagnosis/Management**

While perhaps not as prevalent as in abdominal or gluteal-based breast reconstruction, seroma formation represents a potential risk and drains should be placed at the time of surgery. Seromas are treated when symptomatic with aspiration under sterile conditions and/or closed suction drainage. Occasionally, a seroma may be refractory to serial aspiration and sclerosing therapy or seroma cavity excision may be necessary. Additionally, formation of a lymphocele in this area may be considered in the differential for persistent, refractory fluid collections.

Contour Deformity

Diagnosis/Management

Contour deformity of the upper thigh may be of particular concern to the patient (Figure 24). Contour deformities may be addressed with liposuction or lipofilling as indicated. Deformity of the vulva due to excessive tension at the closure is difficult to treat. Placement of the scar below the groin crease minimizes this deformity but leads to a more visible scar. Careful pre-operative discussion regarding these risks is vital.

Figure 24. Medial thigh contour irregularity and scarring following a tranverse upper gracilis (TUG) flap.

Gluteal-Based Flaps

Bleeding

Diagnosis/Management

Special mention of bleeding risks, particularly intraoperative bleeding is central to discussion of gluteal-based flaps. Great care must be taken when approaching the proximal portion of the gluteal artery at its origin from the internal iliac artery, as there is an extensive surrounding venous plexus (ominously referred to as Medusa's Head). Bleeding occurring in this vicinity can be significant and it is often deep and difficult to reach and control.

Nerve Injury

Diagnosis/Management

The sciatic and posterior femoral cutaneous nerves take a course exiting from between the piriformis and superior gemellus and may be especially prone to irritation or injury while harvesting an inferior gluteal artery perforator flap, as the sciatic nerve travels with the vascular pedicle. Rough handling of this nerve can be a cause of great discomfort with the patient for months after surgery.

Figure 25. Superior gluteal artery perforator (SGAP) donor site. Patients should be counseled regarding scarring and resulting contour irregularity in the donor site.

Buttock Distortion

Diagnosis/Management

While superior gluteal artery flaps are thought to provide a form of buttock-lift, often the change in contour is not in line with a patients' expectations (Figure 25). Particular care must be taken regarding contour irregularity associated with the inferior gluteal artery flap, as it may efface the inferior gluteal crease and pull the buttock down. This deformity is much harder to hide under clothing.

Seroma

Diagnosis/Management

The gluteal donor sites are notorious for seroma formation. Often in order to prevent this, drains are left in place for two to three weeks.

Complications Related to Prolonged Surgical Time

Myocardial infarction: Appropriate preoperative evaluation and optimization are essential to prevention of complications related to prolonged surgical time.

Cerebrovascular accident: Appropriate preoperative evaluation and optimization are essential to prevention of complications related to prolonged surgical time.

Venous thromboembolism: Preoperative, as well as postoperative chemical and mechanical DVT prophylaxis are critical to the care of the free flap patient.

Pressure ulcers: Pressure ulcer formation can occur within hours [49]. Appropriate padding of all bony prominences is important to preventing this untoward complication.

Compressive neuropathies: Finally, the surgeon must be aware of proper padding and positioning of both arms and legs in order to prevent or minimize this uncomfortable complication.

CONCLUSION

Free flap reconstruction is a common and well-established method for breast reconstruction. Although the flap selection, microsurgical technique and countless other variables may change, the general approach to diagnosing and managing free-flap complications remains the same. Key to this is a logical and algorithmic approach to the early and late problems seen in free-flap reconstruction.

Chapter 180

THE EFFECT OF SLEEVE GASTRECTOMY ON METABOLIC COMORBIDITIES

Jaime Ruiz-Tovar*, MD, PhD and Carolina Llaveró†

Obesity Unit, Clinica Garcilaso, Madrid, Spain

ABSTRACT

Impaired glucose tolerance, hypertension, and dyslipidemia have been described as metabolic syndrome (MS). MS is associated with an increased cardiovascular risk, and a close association between morbid obesity and MS has been highlighted in several clinical studies. Disease risk increases with increasing body mass index (BMI). Bariatric surgery has been shown to be effective in achieving and maintaining weight change and reducing obesity related comorbidities.

Sleeve gastrectomy (SG) is a restrictive bariatric procedure that involves subtotal gastric resection of the fundus and body to create a long, tubular gastric conduit constructed along the lesser curvature of the stomach. There is little long-term information available because this procedure has only recently been used as a primary weight loss surgery procedure.

Recent reports have shown that SG may have similar resolution rates of the MS and a weight loss curve similar to that of the Roux-en-Y bypass. In this chapter we will review the available evidence about the remission of diabetes mellitus, dyslipidemia and hypertension after SG.

INTRODUCTION

Impaired glucose tolerance, hypertension, and dyslipidemia have been described as metabolic syndrome (MS). MS is associated with an increased cardiovascular risk [1], and a close association between morbid obesity and MS has been highlighted in several clinical studies. Disease risk increases with increasing body mass index (BMI) [2, 3]. Bariatric

† Carolina Llaveró, RN.

surgery has been shown to be effective in achieving and maintaining weight change and reducing obesity related comorbidities [4].

Sleeve gastrectomy (SG) is a restrictive bariatric procedure that involves subtotal gastric resection of the fundus and body to create a long, tubular gastric conduit constructed along the lesser curvature of the stomach. There is little long-term information available because this procedure has only recently been used as a primary weight loss surgery procedure. It was originally described as a first-stage bariatric procedure followed by Roux-en-Y gastric bypass or duodenal switch in high-risk patients.

However, with the benefit of low risk due to less invasiveness, ease of surgery, and success in terms of sustained weight loss, surgeons have accepted SG as a primary bariatric procedure. Most bariatric surgeons calibrate the sleeve with 32-40F bougies, and the use of smaller diameter bougies is associated with higher weight loss rates [5-7].

SG not only reduces the volume of the stomach, which makes it a restrictive procedure, but also changes gastrointestinal hormone levels such as serum ghrelin, peptide YY (PYY) and glucagon-like peptide 1 (GLP-1). Recent reports have shown that LSG may have similar resolution rates of the MS and a weight loss curve similar to that of the Roux-en-Y bypass [8-10]. However, there is still little mid- and long-term information available about the metabolic effects of SG.

EFFECT OF SLEEVE GASTRECTOMY ON TYPE 2 DIABETES MELLITUS

The mechanisms underlying type 2 diabetes mellitus (T2DM) remission following SG have yet to be fully determined, but some studies have reported favorable changes in insulin sensitivity [11]. Abbatini et al. [12] have demonstrated a near-normalization of insulin resistance in patients treated with SG. The improvement in insulin sensitivity is thought to be primarily due to weight loss, reduction in inflammatory mediators, and decreased caloric intake, although the contribution of weight-independent mechanisms seems very likely. In our recently published study, we could not demonstrate a correlation between weight loss and reduction in glucose levels [13]. It has been established that diabetes improvement appears before a significant weight loss occurs [14]. Despite a progressive reduction of glucose levels in our case series, this did not achieve statistical significance up to 3 months after surgery; however, it was associated with a loss of excessive BMI by 45.6%.

Some authors have reported glycemic control in >80% of patients after 1 month. In our series, including diabetic and euglycemic patients, significant differences from preoperative glucose values could only be observed after 3 months. However, 83.3% of our diabetic patients discontinued their hypoglycemic medication after 1 month, similar to other reported findings [13, 14]. The exclusion of the proximal small intestine was initially thought to play a major role in the rapid improvement in the metabolic control of diabetes. Therefore, malabsorptive or mixed bariatric procedures were considered to be much more effective than purely restrictive ones. In this way, additional mechanisms, such as ileal interposition, have been added to sleeve gastrectomy with the aim of achieving better metabolic results [15].

However, diverse studies have demonstrated that SG as a unique bariatric procedure, compared with Roux-en-Y gastric bypass, achieves similar improvements in the glucose homeostasis [9, 16, 17]. Some studies have shown that SG is associated with a marked

reduction in the secretion of ghrelin, an orexigenic peptide produced by the gastric fundus and involved in mealtime hunger regulation. Ghrelin also exerts several diabetogenic effects (increases in somatotropin/growth hormone, cortisol, and epinephrine); therefore, its suppression could contribute to improve glucose homeostasis [18, 19]. Previous studies have shown diabetes resolution occurring in 66-80% of patients undergoing SG, and the maintenance of reduced plasma levels after 15 months follow-up. In our series, the short-term results are in line with those described in the literature, and good glycemic control persisted after a minimum follow-up of 24 months [13], thus confirming the midterm effectiveness of glycemic control described by other groups [10,19].

EFFECT OF SLEEVE GASTRECTOMY ON LIPID PROFILE

Diverse studies have shown a significant reduction in cardiovascular risk, with increased high-density lipoprotein (HDL) cholesterol and decreased triglycerides after 1 year [7, 20]. As with glucose homeostasis, there is also a lack of long-term results describing changes in the lipid profile. One year after surgery, increases in HDL of 12% and reductions in triglycerides of up to 23% have been described. We have observed an increase of 30% in HDL levels and a reduction of >60% in triglyceride levels, and these levels were maintained after a minimum follow-up of 24 months; however, total cholesterol and low-density lipoprotein cholesterol levels were not significantly changed. A relationship between lipid profile changes and weight loss or BMI changes during followup could not be demonstrated [13].

Low serum lipid profiles in morbidly obese patients may be affected by alterations in the expression of a recently described receptor that mediates the absorption of dietary cholesterol in the intestine; abnormal intestinal flora; or serum leptin levels [7, 21, 22]. Our data highlight this paradox, with SG achieving an excess BMI loss of 76.9% in 1 year and no change in total cholesterol values [13]. Increases in serum cholesterol have even been noted during the weight loss period, with cholesterol being mobilized from adipose tissue as it is metabolized [7].

It has been known for more than 40 years that some extremely obese subjects have normal serum cholesterol, although they still have a high cardiovascular risk [23]. On the other hand, weight loss is associated with a lower cardiovascular risk. This means that other cardiovascular risk factors must improve after weight loss. The triglyceride:HDL ratio has been described as one of the strongest predictor of a heart attack and of other cardiovascular complications [24]. Ratio levels >4 are associated with a high cardiovascular risk. In our patients, we observed a significant reduction in this ratio from 4.2 to 3.5 after 1 year, which was maintained at 3.4 2 years after surgery [13]. The triglyceride:HDL ratio has been proposed as an early marker of insulin resistance, which improves with SG. The improvement in diabetes could be one of the factors contributing to decreased cardiovascular risk. Vila et al. [25] recently reviewed published studies about lipid changes after different types of weight loss surgery, but there were no data on sleeve gastrectomies. In general, malabsorptive procedures improved all variables of the lipid profile, while the restrictive procedures tended to primarily increase HDL and reduce triglycerides, as we observed for SG. However, decreased global cardiovascular risk was similarly observed following both restrictive and malabsorptive procedures.

EFFECT OF SLEEVE GASTRECTOMY ON HYPERTENSION

Obesity surgery also improves hypertension. Slight weight loss is associated with a significant reduction in blood pressure values. Following Buchwald classification, an excess weight loss of 1% correlates with a reduction of 2 mmHg in diastolic blood pressure [26]. Different studies have demonstrated that bariatric surgery globally reduces hypertension rate to 50%, represented as treatment discontinuation and a 25% reduction in the amount of antihypertensive drugs needed [27]. In contrast to effects on T2DM, improvements in blood pressure values are achieved several months postoperatively.

Moreover, the improvement in hypertension seems to be independent of the bariatric technique performed, although a greater reduction is obtained in those patients with greater weight loss [28]. Resolution of hypertension has been described in 43% of cases following adjustable gastric banding, in 69% after gastric bypass, and in 83% after biliopancreatic diversion. Surprisingly, in our series of morbidly obese patients undergoing SG with a hypertension rate of 30%, this comorbidity showed complete resolution in all patients (100%), allowing discontinuation of all antihypertensive treatment 6 months after surgery. We observed a mean reduction of 37 mmHg in systolic blood pressure and of 19 mmHg in diastolic blood pressure; however, this reduction did not show any correlation with weight loss. We cannot currently explain these extraordinary results in our patients.

THE LEFT-HANDED SLEEVE GASTRECTOMY: THE TECHNIQUE TO AVOID POSTOPERATIVE GASTRIC STENOSIS OR GASTRIC TWIST

Pierre Blanc^{*} and Christophe Breton[†]
Clinique chirurgicale mutualiste, Saint-Etienne, France

ABSTRACT

Background Laparoscopic sleeve gastrectomy (LSG) is an effective bariatric procedure. The objective of this study is to describe a series of patients who were subjected to LSG without post operative gastric stenosis (GS) or gastric twist (GT). *Methods* From January 2011 to October 2015, 200 patients with morbid obesity underwent LSG in our institution. Out of 200 patients, 160 (80%) were women. The mean age was 44 years with a BMI of 40,4 kg/m² (35 to 70). *Results* The mean age was 44 years (range 20-67), with a mean initial BMI of 40,4 kg/m² (range 35-70). From the 200 patients who underwent LSG, 160 (80%) were women. The average operative time was 60 minutes, and the mean hospital stay was 3 days (range 2-5). There were two fistulas at the upper part of the sleeve that required endoscopic treatment, and there were two haemorrhages with one that required a surgical treatment. No GS or GT was found. No mortality was reported during the follow-up (range 1month-2 years). Average weight loss at 2 year was 35 Kg (30 to 80). *Conclusions* To avoid gastric stenosis or gastric twist during sleeve gastrectomy, the technique must be meticulously standardised. To avoid these rare complications, the fundus should be well mobilised and the stomach should be divided with the stapler inserted through a trocar placed on the midline (the left-handed technique), directed toward the angle of His, so no angulation of the stapler would be required.

INTRODUCTION

Laparoscopic sleeve gastrectomy (LSG) in morbid obesity has proved to be a safe and reproducible technique [1, 2]. LSG has become an integral part of the surgical treatment for morbid obesity, and it is being recognized as a valid stand-alone procedure for the surgical management of morbid obesity. LSG, however, is not free of complications [3]. The occurrence of gastric stenosis (GS) or gastric twist (GT) has been rarely published [4]. The purpose of the present study is to describe our technique and the tips and tricks to decrease the risk of these complications.

MATERIALS AND METHODS

From January 2011 to October 2015, 200 patients with morbid obesity were included in a prospective protocol and underwent LSG at the department of bariatric surgery, Clinique Chirurgicale Mutualiste, Saint-Etienne, France.

The patients were eligible for bariatric surgery according to the French National Institute of Health's criteria for bariatric surgery (H. A. S.), which include patients with a body mass index (BMI) of 35 kg/m² and associated comorbidities or a BMI of 40 kg/m² and who have failed conservative management.

All patients were evaluated preoperatively by a multidisciplinary team including an endocrinologist, a psychologist, a dietician, a bariatric nurse and a surgeon. All patients underwent preoperative screening, including physical examination (comorbidities, use of medication, BMI), nutritional status (laboratory tests), psychological examination, screening for obstructive sleep apnea, preoperative upper endoscopic evaluation, preoperative abdominal tomography and a preoperative upper gastrointestinal study. The exclusion criteria were the presence of severe esophagitis, Barrett's esophagus, hiatal hernia, as well as the presence of alcoholism, drug addiction, or psychological disorders.

Surgical Procedure

The surgeon stands between the legs (French position). The abdomen is entered under direct vision, without previous insufflation, using Kii-Fios© first entry trocar (Applied, Rancho Santa margarita, CA) on the left midclavicular line. LSG is performed using three to five ports (Figure 1). The greater curvature is mobilized using Harmonic Scalpel (ACE 45©, Ethicon endosurgery, Cincinnati, OH). The left crus is exposed and the lipoma of the angle of His is not removed in order to avoid stapling the esophagus. The gastro-pancreatic adhesions are dissected to have good mobilization of the stomach. The linear stapler (Echelon© or PowerEchelon©, Ethicon endosurgery, Cincinnati, OH) is used only with the left hand, through the port located 18 cm under the xiphoid process on the midline (Figure 2). Before dividing the stomach, the anesthesiologist introduces a 37-F bougie MID-Sleeve© (Medical Innovation Developpement, Dardilly, France) inside the gastric lumen up to the antrum. The balloon of the MID-Sleeve© is placed in the antrum and insufflated with 40 ml of water. The stomach is divided along the gastric tube, in order to do a reproducible technique and to avoid

any narrowing of the tubular stomach. The stapler is placed at the end of the vessels along the lesser curvature (Figure 3). The gastric tube calibration is mobilized before each gastric section. We begin the division of the stomach 6 cm from the pylorus up to 1 cm from the angle of His using one 4,8 mm green staple and four to five 3,8 mm gold staples, leaving a gastric tubular pouch with a capacity of 120 ml (Ethicon endosurgery, Cincinnati, OH). In all patients, a methylene blue test under pressure (120 ml) was performed to test the permeability of the stapler line and to check for any GS or twist. The specimen is removed through the patient's medial trocar which is dilated digitally. The patient can drink water 6 hours after the surgery and can eat homogenized food on the first postoperative day. Furthermore, elastic compression stockings and subcutaneous low molecular weight heparin injection is administrated until 2 weeks postoperatively. A proton pump inhibitor (esomeprazole 40 mg) is prescribed for 6 weeks to prevent marginal ulcer formation. Outpatient clinic visits are scheduled at, 1, 4 and 12 months and then every year.

Figure 1. Port placement.

Figure 2. The operating room table is placed in the reverse-trendelenburg position at a 20°-30° angle. The stapler is used with left hand.

RESULTS

The mean age was 44 years (range 20-67), with a mean initial BMI of 40,4 kg/m² (range 35-70). From the 200 patients who underwent LSG, 160 (80%) were women. The average operative time was 60 minutes, and the mean hospital stay was 3 days (range 2-5). There were two fistulas at the upper part of the sleeve that required endoscopic treatment, two haemorrhages with one that required a surgical treatment. No GS or GT was found. No mortality was reported during the follow-up (range 1month-2 years). Average weight loss at 2 year was 35 Kg (30 to 80).

DISCUSSION

LSG has recently emerged as a reproducible surgical technique with good results regarding weight loss and resolution of comorbidities [1, 2]. The technique is well described in the literature [5-7]. Realization of a small gastric sleeve seems to be important for a better result regarding weight loss and to decrease the likelihood of dilatation of the tube, have according to the Laplace law, less chance to dilate.

LSG have to leave the stomach with no fixations along the entire greater curvature and the posterior wall of the stomach. The LSG is a technically easier intervention than the gastric bypass or duodenal switch but, but it still requires an experienced bariatric surgeon. In order to realize a tight sleeve, three technical features are critical: first a complete mobilisation of the gastric fundus with a full exposition of the left crus, second the posterior proper traction on the dorsal layer of the stomach when placing the linear stapler (to avoid realization of a wide gastric sleeve), third firing of the linear stapler at the end of the vessels located on the lesser curvature, and slightly lateral to the angle of His (to avoid lesion of the esophagus). The complication rate for LSG has been 2,9%-15,3% with an overall reported mortality rate of 0,1-0,39% according to recent studies [3]. Among the complications which occur following a LSG, GS or GT are uncommon complications (ranges from 0,1 to 3,9%); however, when they occur, they can cause either obstruction through the gastric lumen or delayed gastric emptying [4]. In our study, no GS or GT was found. The major tip to avoid a GT is to think that the LSG is a « left-handed technique.” Indeed, the surgeon has to use the stapler only with the left hand through the port located in the midline (Figure 2). We advise to completely divide the posterior pancreatico-gastric adhesions and to expose the left crus during the greater curvature dissection. It is important to free the upper part of the retroperitoneal fundus from the left crus. The stretch of the stomach should not to be too much and must be the same between the anterior wall and the posterior wall of the stomach. The anatomical landmarks are the end of the short vessels on the lesser curvature (Figure 3). The twisting may also occur by misalignment of the staples in the same plane. With the left handed technique, at the end of the stapling, the gastric section is in a horizontal plan (Figure 4-5). According to the literature GS can be produced by sharp angulations of the stapler. With the left handed technique, there is no need to use the angulation and this risk is minimised. The use of a small calibration tube or the stapling without a tube could also result in GS. Therefore, to avoid a GS, we recommend the stapling to be performed along a specific 37 Fr MID-sleeve© calibration tube mobilized before each stapling.

Figure 3. The stapler is placed against the endoluminal bougie. The posterior wall of the stomach is gently grasped and pull anteriorly.

CONCLUSION

To avoid gastric stenosis or gastric twist during sleeve gastrectomy, the technique must be meticulously standardised. To avoid these rare complications, the fundus should be well mobilised and the stomach should be divided with the stapler inserted through a trocar placed on the midline (the left-handed technique), directed toward the angle of His, so no angulation of the stapler would be required.

CONFLICT OF INTEREST

The authors declare that they have no conflict of interest.

Ethical Approval

All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Informed Consent

For this type of study, formal consent is not required.

Chapter 182

WEIGHT REGAIN FOLLOWING SLEEVE GASTRECTOMY

Melanie Lauti*, Andrew G. Hill and Andrew D. MacCormick

Department of Surgery, South Auckland Clinical Campus,
University of Auckland, Auckland, Middlemore Hospital, New Zealand

ABSTRACT

Weight regain has long been recognised as a complication of bariatric surgery with recent work suggesting that it may be most common following sleeve gastrectomy. Weight regain is an important complication due to its association with recurrence of diabetes, deterioration in quality of life and economic implications. Despite this, weight regain remains inconsistently reported and poorly understood.

The phenomenon of weight regain following bariatric surgery has no consensus definition. In the small number of series where it is reported, the definition may be any weight regain or an increase in an arbitrarily chosen value such as an increase of 10kg, 5kg/m² or 25%EWL from the post-operative weight loss nadir. The result is that reported rates of regain vary from 6% at two years to 76% at six years post-operatively.

The causes of weight regain after sleeve gastrectomy have not been definitively established. A systematic review revealed five possible contributors: technical factors, sleeve dilatation, ghrelin levels, maladaptive lifestyle behaviours and lack of adequate follow-up support. Further studies are required to understand the underlying mechanisms definitively.

The management of weight regain following sleeve gastrectomy is not well described. Management guidelines are difficult to formulate given the variability in definition, incomplete understanding of its etiology and lack of robust evidence for revision procedures. Currently, management varies from observation to major revision surgery and is generally tailored to the patient and is dependent on the options available at the treating bariatric service.

Weight regain following sleeve gastrectomy is a common complication with significant implications. To date, its understanding and management have been hampered by the lack of a standardized definition and paucity of robust studies. Once these issues

* Corresponding Author's Email: m.lauti@auckland.ac.nz.

are addressed, the identification and management of weight regain following sleeve gastrectomy will be able to be optimised.

Keywords: sleeve gastrectomy, weight regain

INTRODUCTION

Weight regain following bariatric surgery is a well-recognised phenomenon of long-term outcome reporting. The Swedish Obese Subjects (SOS) study was the first long-term, prospective controlled trial to observe and compare the effects of bariatric surgery to usual care [1]. In their study that included over 2,000 patients undergoing bariatric surgery, weight regain began in the second year then tended to level off after eight to ten years through to twenty years. The applicability of these results to contemporary bariatric practice must be interpreted with the knowledge that this study population used different surgical selection criteria to those currently recommended and the majority of the study population underwent the now obsolete vertical banded gastroplasty (VBG). Furthermore, the attrition after ten years of follow-up was significant. More relevant to current practice is the Utah-based prospective study that compared long-term weight loss in the severely obese undergoing Roux-en-Y gastric bypass (RYGB) with those who had no surgery [2]. In this study, an excellent follow-up rate of 93% of the original 418 surgical patients was obtained. Their results demonstrated a 7% (95% CI 5%-10%) increase in mean unadjusted weight loss from year two to six following surgery. It appears that weight regain following bariatric surgery is a phenomenon common to all procedure types. Recent work, however, suggests that the proportion of patients who regain weight following sleeve gastrectomy (SG) may be higher than after RYGB [3].

The significance of weight regain following bariatric surgery is unclear. Even in the presence of the weight regain outlined above, bariatric surgical recipients still overall reap the benefits of reduced incidence of diabetes, cardiovascular disease and overall mortality as well as significant rates of diabetes remission [1, 2]. When the relationship between weight regain and comorbidities is further explored, however, important trends emerge. Brethauer et al. (2013) reported on a Cleveland Clinic cohort of 162 diabetic patients who had undergone a RYGB on average five years previously with remission rates of 71% and 61% in the short- and long-term respectively [4]. They further demonstrated that diabetes recurrence following partial or complete remission was associated with an increase in body mass index (BMI) of 5kg/m² or more following the weight loss nadir (OR 13, 95% CI 1 – 99).

The SOS study employed a battery of generic and condition-specific quality of life (QOL) measures to assess health-related quality of life (HRQL) at regular intervals over ten years following bariatric surgery [5]. The pattern of change in HRQL largely followed that of weight change over the same period, particularly in mental well-being domains. That is, a gradual reduction in HRQL was associated with the slow weight regain occurring between one and six years post-operatively. Importantly, and similarly to the metabolic effects however, overall HRQL net gains were noted in all domains at ten years when compared to baseline.

Bariatric surgery is a cost effective approach to the treatment of obesity, particularly in diabetic patients [6, 7]. How weight regain affects these estimated cost benefits is less clear

and has previously not been incorporated into economic analyses. Sheppard et al. (2013) attempted to elucidate the direct costs of weight regain by systematic review [8]. Their efforts were hampered by a lack of adequate reporting with respect to regain rates, cost of revision procedures and relevant Canadian literature. They conclude that economic analyses to date have not incorporated the financial impact of assessing and managing weight regain which is likely to have a significant effect on the cost effectiveness of bariatric surgery as a treatment for obesity. Certainly, simulation modelling has confirmed that weight regain could significantly affect cost effectiveness [9].

Weight regain following bariatric surgery is likely to have important consequences with respect to diabetes, HRQL and health economics. The magnitude of these effects, however, remains uncertain given the paucity of the literature that specifically investigates the weight regain phenomenon.

DEFINITIONS AND RATES

Despite the recognised phenomenon of weight regain following sleeve gastrectomy, there are no reporting guidelines nor standardised definitions endorsed by relevant societies. Thus the existing literature is heterogeneous such that it is difficult to know exactly what clinicians mean by weight regain, what a clinically significant amount of weight regain is and how common the problem is. Table 1 presents the currently employed weight regain definitions and Table 2 the weight regain rates for sleeve gastrectomy series with at least two years of follow-up.

Interestingly, the most commonly employed definition in the literature, an increase of greater than 10kg from nadir (Table 1), differs from that most commonly employed by bariatric experts [24]. The International Bariatric Club (IBC), a group of recognised experts in bariatric surgery, responded to a social media poll using the definition for weight regain following sleeve gastrectomy as achieving a BMI > 35kg/m² [24, 25]. Neither of these definitions are ideal. The first does not define the significance in the individual, nor does it allow for comparisons and has even been described as random by those who employ it [26]. The second definition is a flawed static measure [27], assumes a nadir weight of below 35 and is unsuitable for low BMI bariatric cohorts. These points further emphasise the need for an expert group consensus regarding the definition for weight regain.

A further difficulty concerning definitions is that the term ‘failure’ in the literature has been used to refer to progressive weight regain, insufficient weight loss and even symptomatic reflux. Oftentimes, these terms are lumped together, grouping patients together for revision surgery when in fact they are likely to have very different underlying mechanisms causing ‘failure’. Until care is taken to standardise these reporting terms in the bariatric literature, there will be ongoing difficulties in interpreting the evidence that is available.

Despite the plethora of published sleeve gastrectomy series, only a minority report weight regain rates (Table 2). The weight regain rate refers to the proportion of patients who increase their body weight from the nadir achieved following bariatric surgery. Table 2 clearly demonstrates the heterogeneity of the available literature. The series tend to be small, have different patient cohorts, differ in surgical technical and post-operative care and variably define how they categorise patients as having regained weight. The only trend demonstrated

by these series is that the proportion of patients with weight regain tends to increase with the time from surgery. Again, the lack of standardised reporting makes any further generalisations impossible.

Table 1. Weight regain definitions employed in the literature for sleeve gastrectomy series with at least two years of follow-up (updated from Lauti et al. [10])

Origin of definition (author, country, year [ref])	Definition reported
Abdallah et al., Egypt, 2014 [11]	An increase of body weight of more than 10kg
Bohdjalian et al., Austria, 2010 [12]	An increase of body weight of more than 10kg
Braghetto et al., Chile, 2012 [13]	Greater than 10kg
Brethauer et al., United States, 2013 [4]	An increase in BMI of 5kg/m or more above the weight loss nadir
Carmeli et al., Israel, 2015 [14]	Regaining of weight after successful loss defined as a BMI > 35kg/m ²
Casella et al., Italy, 2016 [15]	Weight increase > 10kg from weight loss nadir
de Hollanda et al., Spain, 2015 [16]	The difference between body weight at last follow-up and nadir weight and expressed in kilograms or as a percent of maximal WL
Homan et al., Netherlands, 2015 [17]	25% EWL regain with respect to the minimal weight after LSG or when a patient met the criteria for bariatric surgery again, established by the International Federation for the Surgery of Obesity
Jimenez et al., Spain, 2012 [18]	Any weight regain after T2DM remission to last follow-up
Langer et al., Austria, 2010 [19]	An increase in body weight of more than 10kg from the nadir
Liu et al., Hong Kong, 2015 [20]	%REWL was greater than 25% where %REWL is the percentage of rebound in excess weight loss calculated as the percentage difference between the %EWL measured and the best %EWL achieved during post-operative follow-up
Nedelcu et al., France, 2015 [21]	After an initial successful weight loss (defined as EWL > 50%)
Obeidat et al., Jordan, 2015 [22]	An increase in body weight of more than 10kg from the nadir
Quezada et al., Chile, 2016 [23]	EWL ≤ 50% after having EWL > 50%

Ref, reference; kg, kilograms; BMI, body mass index; m, metres; WL, weight loss; EWL, excess weight loss; LSG, laparoscopic sleeve gastrectomy; T2DM, type II diabetes mellitus; REWL, rebound in excess weight loss.

ETIOLOGY

The aetiology of weight regain following sleeve gastrectomy is not definitively understood. A recent systematic review summarised the proposed contributors to this problem currently discussed in the literature [10]. These were technical factors, sleeve dilatation, hormonal factors, lack of follow-up support and maladaptive lifestyle behaviours pertaining to diet and exercise. Unfortunately, no studies have robustly investigated any of these proposed mechanisms and it appears the aetiology of weight regain is likely multifactorial.

Technical Factors

Technical factors refer to operative technique that influences the initial sleeve size. Specifically, the size of the calibration bougie, the distance from the pylorus where the antrum is divided and ensuring complete excision of the gastric fundus.

From its inception as a component of the biliopancreatic diversion with duodenal switch (BPD-DS) to its evolution as a stand-alone procedure, the remnant sleeve has become progressively smaller [33-35]. Weiner et al. (2007) described their early series initially using no calibration, then a 44F bougie and eventually a 32F bougie as they had noticed an association between larger remnant gastric volume and treatment failure or early weight regain (not defined) [35]. Four years later, this same group decided upon a 42F bougie as their cohort had experienced more staple-line leaks with the smaller bougie [36]. The recent inaugural report from the Metabolic and Bariatric Surgery Accreditation and Quality Improvement Program (MBSAQIP) confirmed an increase in leaks with a calibration bougie size less than 38F and reported better weight loss results (2.45 percentage points of BMI reduction for bougie size ≥ 40 , $p < 0.001$) with larger bougies but weight regain was not assessed [37]. Interestingly, expert consensus has increased the average size of the bougie to 36F due to the increasing belief that leaks are increased with the narrower sleeves [38, 39]. Due to the design and reporting of studies investigating the effect of bougie size, the true relationship between weight regain and bougie size remains unknown [40-43].

The second technical factor contributing to weight regain proposed in the literature relates to where the antrum is divided in relation to the pylorus. In 2011, Weiner et al. (2011) proposed that a dilated antrum acted as a new reservoir within two to four years in patients with weight regain when the distal resection margin of the stomach was 4-6cm from the pylorus [36]. This has been further investigated by two short-term studies. A retrospective study reported 22% of 110 patients regained at least 10kg from their nadir weight when the stomach was divided 6cm from the pylorus compared to only 4% when the division occurred 2cm proximal to the pylorus ($p = 0.003$) at two years [22]. A similar, though not statistically significant, finding also at two years was reported in a randomized trial of 105 patients where 9% and 2% of patients regained at least 10kg from their nadir weight with a 6cm and 2cm antrum remnant respectively [11]. An adequately powered randomized trial with long-term follow-up would provide definite evidence to confirm that a larger remnant antrum contributes to weight regain.

Himpens et al. (2010) conceptualized the 'neofundus' as a cause for weight regain when too much gastric fundus is left adjacent to the gastro-oesophageal junction when dividing the stomach [32]. They hypothesized that the resulting conical- rather than cylindrical-shaped sleeve is then prone to dilatation due to the relative distal stenosis predisposing to subsequent weight regain. Weiner et al. (2011), however, felt this was a better explanation for early poor weight loss outcomes rather than later regain based on their own series [36]. Unfortunately, it continues to be difficult to elucidate further as published series continue to group insufficient weight loss, progressive weight regain and even general procedure failure together, highlighting yet again the great need for standardised language and reporting in this area [44, 45].

**Table 2. Weight regain rates reported in the literature for sleeve gastrectomy series with at least two years of follow-up
(updated from Lauti et al. [10])**

Author Country Year [ref]	Number of patients	Patient cohort	Mean pre-operative BMI kg/m ² (n)	Bougie size	Antral division from pylorus cm	Follow-up period years	Follow-up schedule	Mean post- operative BMI kg/m ² (n)	Mean %EWL % (n)	Regain rate % (n)	Definition used
Abdallah et al. Egypt 2014 [11]	105	Morbidly obese patients aged between 18-60 years	51.7 (105)	38	2 or 6	2	2 weeks then 3, 6, 12 and 24 months	NR	66.5 (105)	5.7% (6)	More than 10kg from nadir

BMI, body mass index; %EWL, percent of excess weight lost; NR, not reported.

^a Excludes the four patients converted to gastric bypass – three for weight regain, one for reflux.

^b Excludes the 11 patients who had a duodenal switch between three and six years but includes two resleeve procedures.

^c Of the 53 consecutive patients, 12 patients were unable to be followed-up.

^d In eight of these cases the sleeve was a revision procedure (six following gastric banding and two following vertical banded gastroplasty).

^e 32 patients excluded for not attending follow-up and a further four excluded as they underwent biliopancreatic diversion with duodenal switch for insufficient weight loss within 18 months.

^f Amount of weight regained was between 11-20kg for 27 patients, 21-30kg for nine patients and >30kg for three patients.

^g In 11 of these cases the sleeve was a revision procedure (ten following LAGB and one following gastric stimulation).

^h Four patients excluded, two cases who had acute conversions to RYGB for leak and two subsequent deaths for reasons not relating to bariatric surgery.

ⁱ Excludes 17 converted cases and two deaths from reasons unrelated to bariatric surgery.

^j Includes only the 11 converted cases to (ten to RYGB and one DS) for weight regain

^k Includes only the six converted cases to RYGB for GORD.

Figure 1. Proposed algorithm for the assessment and management of weight regain following sleeve gastrectomy.

While technical factors may certainly play a role in weight regain, the true manner in which they do so is far from elucidated. Currently, the lack of standardised language continues to be a significant barrier which, if improved, could further our understanding in this area. However, achieving high level evidence in this area will always be arduous given the need for prospective randomized trials with long-term follow-up and the difficulties these incur.

Sleeve Dilatation

It seems inevitable that any sleeve will increase in size with increasing time since surgery. Braghetto et al. (2009) demonstrated that a sleeve doubles in size two to three years post-operatively and postulated that this may be a cause for weight regain [29]. Reporting on their cohort at five years, they describe that 15.7% of their patients had regained weight by five years associated with a further increase in gastric volume [13]. However, as they also report a regain rate of 39.5% in their five-year cohort, it remains unclear how much sleeve dilatation truly contributes to weight regain. A recently published series of sleeve gastrectomy cases with ten year follow-up reports weight regain in 58% of patients (31/53) and stated that endoscopy revealed sleeve dilatation as the leading but not mandatory cause for weight regain [26].

Hormonal Factors

The restrictive effect of a sleeve gastrectomy on caloric intake is further enhanced by the loss of hunger mediated by oxygenic ghrelin levels that become reduced with excision of the gastric fundus [46-51]. One small series of twelve patients noted that the three patients who had regained at least 10kg of weight from nadir at five years had slightly higher ghrelin levels than those who did not, though this was not statistically significant [12]. Further studies are needed to explore this mechanism further.

Follow-up Support

The importance of follow-up support or a lack of follow-up support in contributing to weight regain following sleeve gastrectomy has been proposed by several authors [32, 52, 53]. Himpens et al. (2010) noted that weight regain coincided with discharge from follow-up at three years post-operatively [32]. Sarela et al. (2012) proposed that the lifelong follow-up provided by their National Health Service was responsible for less weight regain [52]. Lombardo et al. (2015) concluded that more follow-up visits may reduce weight regain based on a retrospective study comparing a group of patients that had more follow-up visits than the other. Patients themselves have identified follow-up care as an important influence on their ability to maintain healthy nutritional and exercise behaviors to minimize weight regain [54]. To date, however, there have been no randomized trials to clarify the relationship between follow-up care and weight regain.

Lifestyle Behaviors

Lifestyle behaviors contributing to high-energy diets and physical inactivity are implicated in the etiology of obesity itself and thus unsurprisingly have also been identified as potential contributors to significant weight regain following sleeve gastrectomy [55]. Furthermore, patients who have experienced weight regain following sleeve gastrectomy themselves acknowledge that appropriate nutrition and exercise behaviors are the cornerstone to minimizing weight regain [54].

The effect of lifestyle behaviors on weight regain following sleeve gastrectomy has not been comprehensively investigated. In a small series of patients followed-up at five years, Kehagias et al. (2013) attributed a gradual decline in %EWL to maladaptive eating and lack of exercise as assessed by data obtained from annual dietary questionnaires [56]. Keren et al. (2014) developed a lifestyle modification score based on two questions from the Bariatric Analysis and Reporting Outcome System (BAROS) and found this correlated well with lifestyle change and weight loss results [57-59]. Qualitative data from almost 40 patients who had experienced weight regain following sleeve gastrectomy suggests that the ability of patients to maintain healthy lifestyle behaviors beyond the short-term is influenced by health, psychological health, financial status and follow-up support [54]. Prospective studies evaluating behavioral interventions are required to assess the effect of lifestyle modification on weight regain following sleeve gastrectomy.

MANAGEMENT

There is no universally recognized definitive management for weight regain following sleeve gastrectomy. The literature in this area is limited by non-uniform reporting, an incomplete understanding of its underlying mechanism(s) and a lack of robust prospective studies. Furthermore, even though longer term outcome data following sleeve gastrectomy is now being reported, the outcome data for subsequent revision procedures remains largely short-term. What is recognized is that treatment needs to be individualized [39] and that the management options may be limited by a lack of institutional expertise or experience.

Proposed Algorithm (Figure 1)

Initial assessment of a patient with weight regain begins with a review of the case. The preoperative characteristics of the patient including initial weight measures, co-morbidities and psychosocial factors. The operative details need to be considered. These include surgeon experience, bougie size, division of the antrum in relation to the pylorus together with the operative assessment and management of the hiatus. Finally, the post-operative course of the patient must be reviewed. Their weight loss curve needs to be assessed for a rapid weight loss phase, achieving a satisfactory weight loss nadir before the onset of weight regain. Given that the weight loss nadir usually occurs between 12 and 24 months following surgery, it is the authors' view that the need for revision surgery prior to two years is likely to be attributable

to the phenomenon of insufficient weight loss rather than weight regain. Once a clinical picture of significant weight regain has been established, the patient requires investigation.

Investigations for weight regain following sleeve gastrectomy require a multi-disciplinary approach. Surgical assessment requires a barium swallow and/or endoscopy to exclude remnant fundus and grossly dilated sleeve. Sleeve capacity can accurately be assessed by the addition of volumetric studies, however how these are performed and interpreted varies between centres. The remainder of the multi-disciplinary team must investigate the patient for maladaptive lifestyle behaviours pertaining to nutrition and physical activity and contributing psycho-social factors. Ideally such a team should consist of a nurse specialist, dietician, psychologist, exercise physiologist and social worker. Pragmatically, however, this is not always possible and institutions must optimize their resources to the best of their ability.

If both assessment and investigations from surgical and allied health teams reveal no underlying cause(s) for the weight regain, then a more aggressive bariatric procedure should be considered. Most experts would perform a RYGB as the procedure of choice with BPD-DS as second choice [39]. In the instance when an anatomical abnormality is the only potential cause detected, it may be appropriate to consider fundectomy or resleeve gastrectomy (RSG) for retained fundus or large gastric volume. These cases should also include consideration of direct conversion to RYGB as this has the most evidence base. Finally, if a patient has both surgical and non-surgical abnormalities in their assessment, it is the authors' opinion that the non-surgical issues should be addressed in the first instance. Only once behavioural and psychosocial factors have been addressed, should patients proceed to revision surgery to maximise their chance of success.

Revision Surgery

In many instances, patients presenting with weight regain following sleeve gastrectomy may proceed to revision surgery. Although a recent consensus from experts reported RYGB and BPD-DS as the first and second choice of procedure respectively, the reality is that there is a variety of revision procedures being undertaken and these are institution dependent. Unfortunately, as weight regain remains variably defined, is often grouped together with insufficient weight loss or sleeve failure and is not definitively understood, the evidence in this area is limited. What can be stated, however, is that re-operative surgery for weight regain appears to be safe and generally demonstrates improved weight loss and co-morbidity reduction [60]. Complication rates do appear to be higher than after primary bariatric surgery, though the benefits tend to outweigh the risks with appropriate case selection and management [60, 61]. These complication rates vary by expertise/institution and are likely to continue to improve as surgical experience in bariatric revision surgery unavoidably grows.

The terms resleeve and fundectomy are not clearly defined but appear to refer to the same procedure. It was originally safely described in a case report in the context of revising a BPD-DS for weight regain and subsequently as part of the second stage procedure [62, 63]. Himpens et al. (2010) were among the first to publish undertaking this revision surgery in their six year series for isolated SG [32]. Other than stating that two patients successfully underwent a resleeve operation for weight regain with findings of neofundus formation on barium swallow, no further information was given. Nedelcu et al. (2015) has published the largest series of resleeve gastrectomy (RSG) in 61 patients for progressive weight regain (29),

insufficient weight loss (28) or symptomatic gastroesophageal reflux disease (4) following clearance from a multidisciplinary team after a median period of 37 months from SG [21]. To proceed with RSG, radiological findings of an upper gastric pouch dilatation, huge unresected fundus on barium swallow or a gastric tube volume of more than 250ml on CT volumetry was required. Early post-operative complications included a perigastric haematoma and two stenoses all treated with endoscopic stenting. Weight loss results were available for only 33 patients (54%) but did demonstrate reasonable weight loss at a mean follow-up interval of 20 months (range 12-72). Only one series to date has produced a series of RSG specifically for weight regain [64]. Cesana et al. (2014) described 11 patients with progressive weight regain and persistence of comorbidities with associated persistence of gastric fundus and/or antrum on upper gastrointestinal series. However, they identified these patients early within the first two post-operative years, weight regain was not defined and it could be that these patients had insufficient weight loss rather than significant weight regain. Regardless, their results confirmed the feasibility, safety and satisfactory weight loss results for RSG at one year. Longer-term studies with well-defined selection criteria are required to increase the level of evidence in this area.

Generally, expert bariatric surgeons opt for RYGB as the revision procedure for weight regain following sleeve gastrectomy [39]. Certainly, the effectiveness of this operation as a primary procedure is well established [1, 2]. Its role as a revision procedure for weight regain after SG is less clear but has the most amount of evidence of all revision procedures after SG. Langer et al. (2010) were the first to publish a series of SG to RYGB conversions specifically for weight regain [19]. They described revising SG to RYGB in five patients who had regained at least 10kg of weight from the nadir weight and were high-volume non-sweet eaters. The interval from SG to conversion was between 24-63 months and early follow-up suggested this could be undertaken safely with further weight loss. This same group report on their 10 year cohort in which 11 patients underwent conversion to RYGB for weight regain [26]. Again, the conversions appeared to be safe and weight loss results were similar to those who had not required a revision procedure for weight regain suggesting durability. Quezada et al. (2016) corroborated these findings in their SG to RYGB revision series of 50 patients [23]. Twenty-eight of these patients were analysed separately from the indication of weight regain defined as $EWL \leq 50\%$ after having $EWL > 50\%$ and found the revision procedure to be feasible, well-tolerated and render similar weight loss results to non-converted patients at three years in the 72% of patients who were able to be followed up. A prospective trial comparing RSG with conversions to RYGB would significantly increase the level of evidence currently in the literature. Such a study, however, would need to be meticulously designed with well-defined selection criteria and would pragmatically be difficult to undertake with adequate power.

BPD-DS is a radical procedure with a significant malabsorptive component. SG was originally developed as a modification to BPD-DS for the super obese and thus 'revision' of a SG to BPD-DS is not a new concept [33]. Thus its effectiveness for weight loss in higher BMI patients is established [65]. Whilst obesity-related outcomes are better when compared with RYGB, this is at the expense of higher complication and malnutrition rates [66]. The use of BPD-DS as a revision procedure for weight regain following sleeve gastrectomy has a comparatively smaller literature base. Homan et al. (2015) retrospectively reviewed a cohort of such patients where regain was defined as a gain of 25% EWL with respect to the minimal weight after SG, or when a patient met the criteria for bariatric surgery again (as established

by the International Federation for the Surgery of Obesity) [17]. They reported on 25 patients who had undergone secondary surgery because of insufficient weight loss or weight regain with superior weight loss outcomes following BPD-DS, percent of total body weight loss (%TBWL) of 27% (range 7%-50%), compared with 9% (range -16%-35%) following RYGB ($p = 0.004$) after a median follow-up of 34 (range 14–79) months. Furthermore, three patients (27%) patients who underwent RYGB as the revision procedure regained weight. The significance of these results needs to be balanced against the study's retrospective design, small numbers, increased nutritional deficiencies in the BPD-DS group and baseline differences as the patients converted to RYGB had lower pre-revision weight measures than those converted to BPD-DS. Furthermore, the indications of insufficient weight loss and weight regain were analysed together despite their likely different underlying aetiologies. Dapri et al. (2011) reported a small ($n = 26$) retrospective series comparing BPD-DS with RSG also for insufficient weight loss or weight regain (not defined) [67]. BPD-DS was selected for patients with polyphagia and RSG for patients with hyperphagia once psychological disorders had been excluded. They also found superior weight loss outcomes following BPD-DS but again with associated higher rates of complications with mean follow-up of 23 months (range 13–38) in the context of similar limitations to the series of Homan et al. (2015). While expert bariatric surgeons consider the BPD-DS the second choice for revision of SG, there is no robust evidence available supporting this in patients with weight regain following sleeve gastrectomy. Thus when proceeding to BPD-DS, it should only occur in centres experienced in both the procedure and follow-up care to minimise the recognised high rates of complications and malnutrition.

CONCLUSION

Weight regain following sleeve gastrectomy is a common complication with significant implications. To date, its understanding and management have been hampered by a lack of a standardised definition and paucity of robust studies. Once these issues are addressed, the identification and management of weight regain following sleeve gastrectomy will be able to be optimised.

University of Auckland, Auckland, Middlemore Hospital, New Zealand

ABSTRACT

Enhanced Recovery After Surgery (ERAS), or fast track programmes, integrate multiple evidence based perioperative care interventions to standardise and optimise perioperative care. Their use has been shown to reduce perioperative morbidity and, as a result, reduce the length of hospital stay. They have also been shown to be cost effective.

The use of ERAS was initially popularised in colorectal surgery but there is now an increasing volume of evidence demonstrating the effectiveness of ERAS in the setting of bariatric surgery. The early literature reporting on ERAS in bariatric surgery was in the setting of laparoscopic roux-en-Y gastric bypass (LRYGB) where case series demonstrated a reduction in the length hospital stay. However, the use of ERAS has now been evaluated in patients undergoing sleeve gastrectomy (SG) with a recent randomised controlled trial showing a similar reduction in length of hospital stay as well as improved cost effectiveness without increasing perioperative morbidity.

Whilst consensus regarding ERAS constituents was reached in a recent report detailing guidelines for its implementation in bariatric surgery, it is important to know that some recommendations are based on data extrapolated from non-bariatric surgery. Also, length of stay remains only a proxy of surgical recovery and that the aim of ERAS is to reduce perioperative morbidity which should be a primary focus of future studies.

1. INTRODUCTION

Surgical treatment, in the form of Bariatric surgery, is now recognized as an effective treatment for severe obesity [1]. It is the only evidence-based method to significantly improve and sustain weight loss as well as cause resolution of obesity related comorbidities such as type 2 diabetes mellitus (T2DM) [2]. Bariatric surgery includes a variety of procedures, which are mostly performed laparoscopically. The most common procedures performed today are laparoscopic adjustable gastric band and laparoscopic roux-en-Y gastric bypass.

Laparoscopic sleeve gastrectomy (SG) has become an established bariatric procedure effecting weight loss by way of restricting caloric intake as well as reducing plasma levels of ghrelin. There is an established body of evidence showing that SG produces excellent short-term weight loss and is effective at resolving obesity related comorbidities [3-6]. There is also growing evidence showing that these short-term results are sustained at long-term follow-up [7-10].

Despite its effectiveness, the established benefits of SG can come at the expense of significant short-term morbidity. This can significantly impair surgical recovery leading to prolonged postoperative convalescence, increased costs and sub-optimal surgical outcomes such as weight regain and return of obesity related comorbidity [11-15].

Enhanced recovery after surgery (ERAS), or fast track programmes, incorporate multiple evidence-based perioperative care interventions in order to standardize and optimize perioperative care. Initially pioneered in colorectal surgery, ERAS has been shown to reduce perioperative morbidity, reduce postoperative length of hospital stay and reduce costs [16-18]. It has now been adapted in bariatric surgery with the aim to reduce the morbidity and cost associated with various bariatric procedures and there is now an established body of evidence evaluating its efficacy in SG [19].

The aim of this chapter is to discuss the use of ERAS in patients undergoing SG. It will discuss how the concept of ERAS was developed, the perioperative care interventions used and the how it has been implemented in SG.

2. THE DEVELOPMENT OF ERAS

ERAS programmes were initially pioneered by Kehlet et al. in the setting of colorectal surgery [20-22]. They were aimed at addressing the profound inflammatory response associated with surgery. This inflammatory response, characterized by the release of pro-inflammatory cytokines, has been shown to be associated with increased rates of perioperative morbidity and mortality and prolonged convalescence [23].

Optimising perioperative care was postulated as a means of manipulating the inflammatory response to surgery. This was in light of the realization that many of the established and historical perioperative care interventions in practice were outdated and potentially harmful. The inherent biological redundancy of the inflammatory response [24] has meant that single interventions have not been particularly effective. With this understanding, the idea of perioperative care optimization was shifted from looking at the individual effects of perioperative care interventions to the effect that each intervention had collectively on surgical recovery. This idea of collective effect is the basis of ERAS.

ERAS programmes incorporate multiple evidence based perioperative care interventions in order to optimize and standardize perioperative care. They have become an established means of reducing perioperative morbidity, length of hospital stay and costs associated with colorectal surgery. In their randomized trial of ERAS compared to standard perioperative care following hemicolectomy, Anderson et al. demonstrated earlier mobilization and return to diet as well as reduced length of hospital stay [25]. This was similar to the findings of two earlier studies by Delaney et al. and Gatt et al. which found in patients undergoing colectomy, reduced length of hospital stay in ERAS patients compared with non-ERAS patients, including those with significant preoperative comorbidity, without increased readmission rates or complications rates [26, 27]. Varadhan et al. published the results of a systematic review and meta-analysis of six randomized controlled trials, that again showed reduced length of hospital stay following elective colorectal surgery [17]. However, they also reported significantly reduced risk of postoperative complications in patients having surgery within an ERAS programme.

Due to the success of ERAS programmes in the setting of colorectal surgery, their use began to permeate to other surgical specialties. Stowers et al. reviewed the literature reporting the use of ERAS in hip and knee arthroplasty and found reduced length of hospital stay and morbidity [28]. Scott et al. published the review of ERAS in patients undergoing elective hip and knee arthroplasty in Scottish orthopaedic units and found nationwide uptake of ERAS associated with lower blood transfusion rates, earlier postoperative mobilization and shorter length of hospital stay [29]. Cerantola et al. published recommended guidelines for ERAS implementation in patients undergoing radical cystectomy [30]. Wijk et al. reported on their results when implementing an ERAS programme in the setting of elective abdominal hysterectomy and found reduced length of hospital stay without an increase in postoperative morbidity [31].

Mechanick et al. recommended uptake of ERAS in bariatric surgery in their guidelines for perioperative care in the support of the bariatric patient [32]. This subsequently was followed by published reports of bariatric units' experience with ERAS across a variety of bariatric procedures. Though the volume of literature was small, it appeared to provide similar results to those reported in other surgical specialties. McCarty et al. found improved postoperative recovery in patients having gastric bypass after optimizing perioperative care [33]. Bamabagade et al. halved length of hospital stay following laparoscopic gastric bypass [34]. Grantcharov et al. similarly found reduced length of hospital stay following gastric resection within the setting of an ERAS programme but also reported reduced postoperative morbidity [35]. ERAS has subsequently been implemented and evaluated in the setting of patients undergoing SG. Lemanu et al. reported, in their randomized controlled trial, a significant reduction in length of hospital stay without increasing postoperative morbidity or readmission rates. There was also a reduction in hospital costs [19].

3. PERIOPERATIVE CARE INTERVENTIONS

Previous systematic reviews and clinical guidelines have been published with recommendations based on the best available evidence on how to compose an ERAS programme. These guidelines will be summarized in this section. However, it is important to

bear in mind that these recommendations have limitations. Firstly, whilst there is standardization of perioperative care within individual studies, there is significant heterogeneity in the reported literature with respect to the perioperative care interventions which are used when comparing studies resulting in no standardization of ERAS composition between surgical units. Secondly, the evidence for perioperative care interventions used in bariatric surgery is largely extrapolated from data within the colorectal literature.

A summary of the evidence for ERAS in Bariatric surgery has recently been published by the ERAS guidelines group [36, 37].

3.1. Preoperative

3.1.1. Preoperative Counseling and Education

There is a paucity of data that details the effect of preoperative counseling and education on postoperative recovery in the bariatric literature. It has been shown to be effective in the setting of colorectal surgery to reduce anxiety and improve patient compliance to postoperative ERAS protocols. Similar findings have been demonstrated with preoperative ward visits and psychological interventions [38].

3.1.2. Prehabilitation (Exercise, Smoking and Alcohol Cessation, Nutritional Optimization)

Prehabilitation is the concept of initiating the recovery process preoperatively in order to enhance preoperative functional and physiological capacity. It is comprised of three components; preoperative exercise, smoking and alcohol cessation and nutrition optimization [39]. The concept of preoperative exercise is based on the analogy of comparing surgery to a marathon – the fitter you are before the race, the better you will perform and recover. This appeared to translate well in the setting of orthopaedic and abdominal surgery [40-43]. However, the results do not appear to apply as well to patients undergoing bariatric surgery. This may relate to fact that this subgroup of patients are chronically inactive and do not reach a threshold of preoperative physical fitness that is able to be translated into improved clinical outcomes.

Excessive consumption of energy-rich but nutrient-deplete foods causes nutritional deficiency in morbidly obese patients and this can be exacerbated postoperatively due to reduced absorption of nutrients, particularly fat dependent vitamins and trace minerals [44-46]. For this reason, and in order to optimize postoperative dietary behaviour, formal assessment by a dietician preoperatively is recommended.

It is well reported that smoking has significant deleterious effects on postoperative recovery. In particular, it increases the risk of postoperative infection and thromboembolic complications [47, 48]. Guidelines recommend smoking cessation for a minimum of four weeks prior to surgery. Similarly, hazardous drinking poses undue risk of poor outcomes following surgery and it is recommended that patients abstain from alcohol for at least four weeks prior to surgery.

3.1.3. Preoperative Weight Loss

Preoperative weight loss has been shown to be positively associated with postoperative weight loss by Livhits et al. [49]. It is also thought to reduce liver volume improving intraoperative visualization. Most bariatric centres achieve this by enforcing low or very low calorie diet regimes though care must be taken in diabetic patients so as not to induce hypoglycaemia.

3.1.4. Optimisation of Hospital Environment

Whilst there are no published reports in literature detailing the effect of optimizing the hospital environment on postoperative recovery in patients undergoing bariatric surgery, mention has been made by Zargar-Shoshtari et al. suggesting that there was a positive influence of well-lit postoperative wards, which enable and encourage social interaction on patient mood and anxiety levels. This could potentially be reinforced by preoperative hospital visits and familiarization with ward staff prior to admission [38].

3.1.5. Preoperative fasting

Historically, patients are kept nil per mouth for six hours and two hours for solid food and clear fluids respectively. Recent studies demonstrate residual gastric volumes and gastric emptying rates are the same for obese and non-obese patients. Therefore, the recommendation is to maintain preoperative fasting for six hours and two hours for clear fluids in the bariatric setting as in non-obese patients [50, 51].

3.1.6. Carbohydrate Loading

Preoperative carbohydrate loading with iso-osmolar drinks two to three hours prior to surgery is an established practice in colorectal ERAS programmes [52]. It is shown to counteract the deleterious effects of preoperative fasting by attenuating postoperative insulin resistance, reducing protein losses and subsequently maintaining lean body mass. It is safe in diabetic patients and is recommended in patients undergoing bariatric surgery [53].

3.1.7. Glucocorticoid Administration

Preoperative glucocorticoid (GC) administration has been reviewed in other surgical specialties. It attenuates the stress response of surgery leading to reduced length of hospital stay and complication rates [24]. There is less data in bariatric surgery with only a previous case series by McCarty et al. finding preoperative GC to be associated with reduced length of hospital stay [33]. More traditionally, preoperative GC has been used to prophylactically address postoperative nausea and vomiting (PONV). It is also shown to be safe in patients with T2DM.

3.2. Intraoperative

3.2.1. Perioperative Fluid Management

The literature on intravenous fluid (IVF) administration in obese patients largely reports on liberal versus restrictive fluid regimens with earlier non-randomised studies demonstrating reduced rates of postoperative rhabdomyolysis, for which there is a recognized increased

incidence in obese patients [54-57]. However, more recent data would suggest that there is little if in fact in difference in rates of rhabdomyolysis between liberal and restrictive IVF regimes. Instead, proponents of ERAS recommend instigation of early postoperative oral intake as a means to maintain haemodynamic parameters [58]. The literature on the use of goal-directed fluid therapy is sparse but Jain et al. found haemodynamic parameters could be sufficiently maintained when using stroke volume as a guide, which resulted in smaller total fluid volumes being administered without complication [59].

3.2.2. Postoperative Nausea and Vomiting (PONV)

Multimodal antiemetic regimens are strongly advocated and supported by studies reported in the current bariatric literature. The multimodal approach includes the use of a combination of antiemetic agents as opposed to using only one or even two agents, avoiding volatile agents in favour of propofol for induction and maintenance of anaesthesia, reducing excessive IVF administration and avoiding opiates [60-62].

3.2.3. Standardised Anaesthesia

Due to the presence of obesity related comorbidity and differences in physiological parameters, obese patients often provide anaesthetists with significant challenges during the perioperative period. Particular attention must be paid to pressure areas with respect to on table positioning and great care taken to avoid hypothermia [57]. Positive end expiratory pressure can be utilized to improve intraoperative oxygenation and reduce the risk of pulmonary atelectasis [63-65]. Whilst the evidence for neuromuscular block as a means to aid in surgical performance is minimal, there is good evidence to suggest anaesthetic depth monitoring using the bispectral index and ensuring full reversal of neuromuscular blockade does improve surgical recovery [36].

3.2.4. Prophylactic Nasogastric Tube

The literature on the role of prophylactic nasogastric tubes (NGT) showed that they did not confer an additional benefit to the patient postoperatively [66, 67]. There is no difference in the rates of anastomotic leakage when comparing patients with NGT and those without. It significantly impairs time to instigation of oral intake postoperatively, which has been shown to be positively associated with surgical recovery and length of hospital stay, and it is widely recommended that NGT be removed prior to reversal of anaesthesia.

3.2.5. Prophylactic Abdominal Drain

The literature on prophylactic abdominal drainage in the setting of bariatric surgery is sparse with no randomized controlled trials evaluating their efficacy. They are traditionally used to help with both early identification of and facilitate non-operative management of anastomotic leak. However, recent recommendations have suggested that the use of prophylactic abdominal drains is unnecessary based largely on data extrapolated from other abdominal surgical subspecialties [68].

3.2.6. Other Novel Interventions

Various other interventions have been investigated which may be applicable to bariatric surgery. Previous studies have investigated whether warming and humidifying insufflation

carbon dioxide reduces peritoneal inflammation [69]. Whilst there have been shown to be small benefits to surgical recovery in other specialties, there are no data evaluating its efficacy in bariatric surgery. Intraperitoneal local anaesthetic works by blocking nociceptive peritoneal pathways. Its use is supported by a previous systematic review as a means of improving pain and recovery and recovery after abdominal surgery [70]. It was utilized in the ERAS protocol formulated by Lemanu et al. but ongoing research is required to evaluate its efficacy [19].

3.3. Postoperative

3.3.1. Multimodal Analgesia

Similar to the approach to anti-emesis, multimodal analgesia is advocated as the preferred approach to postoperative analgesia by proponents of ERAS. It encourages the use of regional anaesthesia and avoidance of opiates in favour of non-steroidal anti inflammatories, intravenous acetaminophen and local anaesthetic [61]. If opioids are required, it suggested that favour be shown toward utilizing patient controlled regimes with an increased refractory period between doses [71]. Research into the use of medications such as gabapentin or pregablin is ongoing [72].

3.3.2. Supplemental Oxygenation

Whilst the evidence for the use of supplemental oxygen is sparse in the setting of bariatric surgery, it is an important issue to consider due to the high rates of both diagnosed and undiagnosed obstructive sleep apnoea (OSA) as well the relationship between obesity and tissue hypoperfusion and low oxygen tension in subcutaneous tissues [73, 74]. Research into the use of postoperative supplemental oxygenation in the setting of colorectal surgery found a significant reduction in the incidence of wound infection [75]. Further investigation is required to evaluate its efficacy in bariatric surgery though is still strongly recommended.

3.3.3. Early Postoperative Nutrition

Early postoperative nutrition is safe and strongly recommended in the setting of bariatric surgery. It generally involves starting clear fluids only a few hours after surgery and then consultation with a dietician to ensure adequate dietary composition. Generally it is recommended that patients have small but frequent meals with special care taken to maintain adequate fibre and protein uptake and avoiding concentrated sugars which can lead to dumping syndrome. Fluids should be consumed slowly over the course of the day at regular intervals in order to maintain adequate hydration. It is recommended to aim for an intake of approximately 1-1.5L per day [76].

3.3.4. Thromboprophylaxis

Venous thromboembolism (VTE) is a major cause of significant morbidity and mortality following bariatric surgery. It is important to instigate a standardized approach to VTE prophylaxis and ensure that it is well adhered to. It needs to combine early mobilization with both mechanical and pharmacological methods that some authors advocate be used for three to four weeks postoperatively [77, 78].

3.3.5. Non-Invasive Positive Pressure Ventilation

The routine use of continuous positive airway pressure (CPAP) is recommended in patients with diagnosed OSA. However, unless patients are super obese, have oxygen saturations less than 90% with oxygen supplementation or have obesity related hypoventilation syndrome, routine use is not recommended [36].

4. IMPLEMENTING ERAS IN SG

4.1. Current Evidence

There is now an increasing body of evidence evaluating the use of ERAS in the setting of SG. Lemanu et al. published the first and only randomized controlled trial evaluating ERAS versus standard care in patients undergoing SG [19]. They found that patients undergoing surgery within an ERAS programme had a significantly shorter median length of hospital stay of one day compared to two days in the standard care group without an increase in 30 day postoperative complication rates. There was no difference in readmission rate. A comparative analysis was also performed comparing the ERAS and standard care groups to a propensity score matched historical cohort who had surgery prior to the beginning of the randomized controlled trial to account for any cross-over between the two intervention groups and found significant shorter length of stay in the intervention groups compared to the historical cohort (three days) and similar readmission rates. Cost effectiveness analysis also showed significant cost reduction in the ERAS group versus the historical cohort.

Awad et al. published their experience [79] of ERAS in SG. They reported a mean length of hospital stay of 2.3 days with 28% of patients being discharged day one postoperatively. Importantly, they reported low rates of morbidity and a 30 day readmission rate of 2.7%. They concluded that ERAS was safe and effective at reducing convalescence. Lyass et al. also reported their series and had similar experiences with an acceptably low complication rate of 5.7% with no anastomotic leaks or complications requiring re-operation. Readmission rate was also acceptably low at 3.5% [80].

Two studies reported on the experience with ERAS in patients undergoing SG and LRYGB without differentiating the individual results between the two surgical interventions. Mannaerts et al. performed SG in patients with BMI >60kg/m² and reported reduced procedural time, reduced length of hospital stay and increased cost effectiveness [81]. However, they did report an increased complication rate post ERAS implementation that they attributed to increased vigilance in reporting (81). Matlok et al. reported on their consecutive series of LRYGB and SG and found a reduced length of hospital stay (mean of 2.9 days) with no adverse effect seen in complication rates (10.5%) or readmission rates (1.7%) [82].

Barreca et al. also reported on the experience with ERAS in patients undergoing LRYGB and SG. Of the 288 patients they reported on, 65 underwent SG [83]. They reported a complication rate of 6.1% with a readmission rate of 4.6%. Of the 65 patients, 60% were discharged day one postoperatively without an increase in readmission or complication rates when compared to those discharged after two or more days. They concluded by saying ERAS was safe and effective in reducing hospital stay without increasing postoperative complication rates.

4.2. Limitations

It is important to recognize the limitations of ERAS within SG. There is significant heterogeneity in ERAS programme composition between units. This makes it difficult to accurately compare results between bariatric units and this limits accurate evaluation of ERAS efficacy and safety. This limitation has been recognized with ERAS across other surgical specialties.

As has been highlighted previously, ERAS studies, particularly in the early phases of its inception, come predominantly from the colorectal literature. Whilst it is possible to transfer concepts across into the setting of bariatric surgery, it is important to recognize that bariatric surgery procedures may incur different physiological responses than those seen in other surgical specialties. Therefore, what may be effective in colorectal or orthopaedic surgery may not necessarily transfer into bariatric surgery. Similarly and importantly, interventions that may not necessarily be favourable in other surgical settings may in fact provide benefit in a bariatric population, but these interventions may easily be discarded given the only published data on them shows them to be non-efficacious in the non-bariatric setting.

Ongoing evaluation and continued publication of results is an important aspect of quality assessment and control. One of the limitations of the published literature on ERAS, particularly with randomized studies, is an inability to adequately blind participants and medical staff. The effect that this has is there is often cross over between participant groups usually from the non-ERAS group to the ERAS group which can potentially underestimate the effect of ERAS programmes.

A long-term concern is the ability to maintain an effective ERAS programme over time. ERAS involves significant clinical commitment and resource which is often easy to provide in the early stages of development, implementation and follow up. This enthusiasm can wane with attrition, which can lead to sub-optimal results. For this reason, it is important that part of ongoing approach to ERAS performance includes an assessment of compliance to protocol interventions.

It is important to recognize that ERAS does not substitute for clinical judgment. Care providers must be acutely aware that ERAS is a guide to treatment and that a certain level of flexibility must be accounted for when patients are not progressing as expected within an ERAS programme. Treating patients on the basis of their illness must remain a higher priority than compliance to protocol. There is in fact a suggestion that a patient not progressing as expected within the ERAS programme may be an indicator of postoperative morbidity.

Lastly, the ERAS literature reports widely on length of hospital stay and cost-effectiveness. However, it is important to recognize that length of stay and cost are only proxy indicators of surgical recovery. The underlying ethos of ERAS implementation needs to be patient focused with explicit emphasis on putting forward ERAS as a means of reducing perioperative morbidity with length of hospital stay being a secondary outcome.

4.3. Unanswered Questions and Future Directions for Ongoing Research

Whilst the volume of literature evaluating ERAS in SG continues to grow it is important to recognize that unanswered questions remain that can direct further research.

Patient compliance to protocol can influence whether or not they have a successful outcome within an ERAS programme. Novel approaches to improve compliance to protocol at various stages of the ERAS programme may help to improve surgical recovery. One such example is evaluating the use of mobile health technologies such as text-messaging to provide continued encouragement to patients preoperatively to adhere to weight loss instruction or postoperatively to allow an easy means of communication of patients become unwell following discharge with problems which are minor and may not necessarily require readmission to hospital.

The optimal ERAS programme has yet to be composed for patients undergoing SG. Novel interventions to modulate pain may allow increased mobility and greater ability to tolerate oral diet postoperatively. Preoperative exercise has not shown to be effective at improving recovery but this may be due incorrect exercise prescriptions for obese patients who are chronically inactive and further research may evolve prehabilitation into an effective intervention for SG patients.

Only the short-term outcomes of surgery have been evaluated in any depth following SG within an ERAS programme. It is yet unknown whether or not the short-term benefits of ERAS translate into favourable long-term outcomes with no long term follow up weight loss or comorbidity resolution data available. Further research is required to determine what the long-term outcomes of these patients are relevant to the end goal of the surgical procedure.

Finally, by implementing ERAS and standardizing perioperative care, a clinical petrie dish is created that can act as platform for further clinical trials. This benefit of ERAS needs to be better recognized and the potential harnessed to further our understanding of clinical outcomes following SG.

CONCLUSION

In conclusion, ERAS is a concept that appears to have been successfully applied to SG from its initial development in colorectal surgery. The literature evaluating its composition and efficacy continues to grow and despite its limitations remains as an effective method to reduce perioperative morbidity and postoperative convalescence. Ongoing research is required to ensure that ERAS continues to evolve in the setting of SG in order to optimize its efficacy for this group of high-risk patients.

ABSTRACT

There has been a rapid rise in the number of laparoscopic sleeve gastrectomy (SG) for treating morbidly obese patients in the recent few years. This has eventually the most popular bariatric procedure to date. Being only anatomically restrictive, SG has limited effects on glucose homeostasis in type II diabetes mellitus (T2DM) for lack of foregut hormone modulation mechanism. Gastric bypass has been proposed and proven to remit T2DM better than SG due to the foregut exclusion. According to these findings, duodenojejunal bypass (DJB) has been developed to accompany SG to possibly give a better result of diabetes remission than SG alone. The technique DJB-SG involves SG, exclusion of duodenum except the first portion, and bypassing the proximal jejunum. Both the Roux-en-Y and loop fashion for anastomosis of duodenum and jejunum have been adopted. In this chapter, we present both methods of combined SG with DJB as a treatment for morbid obesity and obesity with T2DM.

Keywords: sleeve gastrectomy, duodenojejunostomy bypass, morbid obesity, type 2 diabetes mellitus

INTRODUCTION

The prevalence of obesity is increasing day by day and is the epidemic of the 21st century [1]. In a recent analysis by WHO, it was found that 1.9 billion people aged 18 years or more

were overweight, out of which 600 million were obese. The world obesity population has doubled over the last two decades [2]. Obesity is associated with many diseases. Some of them are diabetes, hypertension, hyperlipidemia, asthma, degenerative bone disease, obstructive sleep apnea, which cause debilitating problems in the obese and add to the cost of health care [3]. Increased body mass index (BMI), abdominal fat and weight gain are important risk factors associated with the development of T2DM. About 90% of people with T2DM are obese [4]. Bariatric surgery is now a well-established procedure for treating morbid obesity and its associated comorbidities.

The evolution of bariatric procedures has progressed over time in an attempt to constantly improve outcomes while minimizing adverse effects. A rapid increase in SG for treating the morbidly obese patients is seen in the recent years. This is becoming the most popular procedure to date owing to its technical simplicity and less malnutrition. It was first performed by Hess in 1988 as a part of the biliopancreatic division [5]. In 1999, Gagner, Jossart and de Csepe developed a laparoscopic approach to duodenal switch (DS), which Gagner later performed in humans [6]. The first international consensus summit for SG concluded that its indications were increasing as a standalone procedure aside from being a part of a staged procedure for the super obese [7].

Recent studies of the biochemical mechanism of bariatric procedures have lead us to understand how anatomical changes in the digestive tract would result in hormonal modifications of decreasing ghrelin and an exaggerated incretin effect. This drives weight loss and improved glucose metabolism [8-12]. Duodenal switch and Roux-en-Y gastric bypass (RYGB) are undeniably more effective for weight loss and diabetes control than SG alone, but not without consequences. Certain anatomical structures are crucial to maintain some physiologic environments to decrease unwanted morbidities. Hess developed the DS with preservation of the pylorus to address the issue of duodenogastric bile reflux as seen in biliopancreatic division patients. This also eliminated marginal ulcers and dumping syndrome [13]. Marceau then used this principle and modified it by cross-stapling the duodenum with an end-to-side duodenoileostomy. The limb lengths were variable and adjusted to have a common limb length of 100cm [14]. Cross-stapling was later discontinued as some patients had recanalization. Thus, an end-to-end duodenoileostomy remained as the standard approach for this procedure. Although DS has one of the best results in weight loss and diabetes control, it is not well tolerated by the Asian population. It is reserved for a very small number of patients due to fear of nutritional complications. On the other hand, RYGB may present with anemia, malnutrition, marginal ulcers and dumping syndrome, which adds to the patient morbidity and may be debilitating.

Duodenojejunal bypass (DJB) was first reported by Rubino and Marescaux in 2004 in an animal model, where bypassing the duodenum and proximal jejunum without gastric restriction achieved glycemic control in nonobese T2DM rats [15]. As an individual procedure, DJB has been also tried as a treatment of T2DM in humans. In 2007, Cohen et al. published DJB to achieve diabetic remission in low BMI T2DM patients, two of which were followed for nine months [16]. A Korean study demonstrated DJB in non-obese patients to exert positive influence on insulin resistance and β -cell function of pancreas. However, the overall effectiveness was not satisfactory as remission was achieved in only 13% of the cases and diabetic improvement was seen in only 27% of cases [17].

Kasama et al. published his case series of DJB-SG in 2009 and was the first to describe DJB-SG in a Roux-en-Y fashion (RYDJB-SG) [18]. The procedure of which is almost similar to a DS with a modification in the size of the gastric tube and the limb lengths [13]. Twenty-one patients with a high risk of gastric cancer were included in the study, as endoscopic surveillance for gastric cancer was feasible. Surgical safety and efficacy for treatment of morbid obesity was established [18]. In 2010, Pernaute et al. published the technique of single anastomosis duodeno-ileal bypass with SG or SADI-S. This is another adaptation of the DS, where the duodeoileostomy anastomosis was done in a loop fashion [19]. In 2011, the SADI-S was further modified as a loop fashion of the DJB-SG (LDJB-SG) and was reported by Huang et al. [20].

MECHANISM OF ACTION

The DJB-SG has two components: the vertical SG and bypassed foregut. It works on the principle of hindgut theory where the proximal 200-300cm jejunum is diverted. Chyme is transported quickly to the distal small bowel to increase the incretin secretion and decrease anti-incretin substances, which would otherwise be secreted from the diverted proximal small bowel. Incretins are the hormones secreted from the hindgut, and anti-incretins are substances secreted from foregut. This concept of hormone secretion from the small bowel playing a role in pancreatic insulin secretion is termed entero-insular axis [8].

The glucagon-like-polypeptide (GLP-1) and peptide YY (PYY) are believed to be the most important incretins and are secreted from the L-cells in the distal ileum and colon in response to meal ingestion. These hormones exercise important glucoregulatory effects, including the glucose-dependent potentiation of insulin secretion by pancreatic β -cells [9]. These are also suppressors of food intake and are known to act on the hypothalamic appetite regulation [10]. Secretion of GLP -1 is increased several fold after gastric bypass surgery, which is postulated to achieve glycemic control by improving β -cell function [11].

Sleeve gastrectomy acts as the restrictive component helping to decrease overall food intake owing to the reduced stomach size. Ghrelin is an enteric peptide known to increase appetite and cause diabetogenic effects by suppressing insulin secretion and glucose metabolism pathways [12]. As ghrelin levels decrease after SG, the diabetogenic effects are likewise decreased and help to achieve better sugar control.

Hormonal Study

Chih-Kun Huang conducted a study on the incretin effect of LDJB-SG in T2DM patients with BMI $<35 \text{ Kg/m}^2$. It was a prospective observational study conducted from May 2013 to March 2014, which included 27 patients, 23 females and four males. The mean age was 51.5 ± 8.6 years, mean weight at $74.5 \pm 13.7 \text{ kg}$, and mean BMI at $28.38 \pm 4.3 \text{ kg/m}^2$. All patients have T2DM with mean duration of 10.2 ± 5.6 years, and underwent LDJB-SG with a 200cm afferent limb. The C-peptide, ghrelin, GLP-1 and PYY were measured over time alongside an oral glucose tolerance test (OGTT).

Hormones were analyzed by calculating time courses, the area under the plasma concentration time profile (AUC), and maximum plasma concentration (C_{max}). Follow-up comparisons were analyzed using the paired t-test. When 20% of the cells had expected values of <5, a Fisher exact test was used instead. All statistical tests were two-tailed and were calculated with SPSS statistical software (version 15.0; SPSS Inc., Chicago, IL). A p-value <0.05 was considered statistically significant.

The LDJB-SG resulted in significant weight loss and good glycemic control. The mean BMI reduced to 22.16 ± 2.75 Kg/m² at six months postoperatively ($p < 0.01$). Fasting sugar and glycated hemoglobin (HbA_{1c}) reduced from 160.66 ± 46.70 gm/dL and $9.31 \pm 1.8\%$ to 111.22 ± 26.64 mg/dL and $6.28 \pm 1.1\%$ at six months ($p < 0.01$).

Ghrelin

At six months, fasting ghrelin levels of 21.99 ± 11.27 pg/mL ($p < 0.05$) were significantly lower than that of the preoperative level 98.58 ± 71.09 pg/mL. Preoperative ghrelin AUC-120 of 82.13 ± 49.36 pg/mL/min dropped to 43.12 ± 26.42 pg/mL/min ($p < 0.05$) and 17.90 ± 9.01 pg/mL/min ($p < 0.05$) at one and six months, respectively. However, the fall was more prominent at six months as signified by a lower AUC and C_{max} (see Figure 1).

Glucagon-Like Polypeptide -1

Preoperative fasting levels of 37.04 ± 54.62 pg/mL reduced to 20.05 ± 15.70 pg/mL ($p < 0.05$) at six months. An exaggerated response was observed at one month as suggested by a higher fasting level of 71.11 ± 66.36 pg/mL ($p = 0.06$) and a C-max of 510.34 ± 292.56 pg/mL ($p < 0.05$). Peak GLP-1 was noted at 30 minutes in all the visits, and AUC-120 increased from 139.37 ± 109.93 pg/mL/min preoperatively to 349.10 ± 187.35 pg/mL/min at one month ($p < 0.05$) and 185.75 ± 118.81 pg/mL/min at six months ($p = 0.06$) (see Figure 1).

Peptide YY

At one month, AUC-120 changed from 137.10 ± 93.20 pg/mL/min preoperatively to 454.50 ± 134.85 pg/mL/min ($p < 0.05$) and 136.57 ± 134.53 pg/mL/min at six months ($p = 0.987$) postoperatively. Preoperative fasting PYY levels of 78.91 ± 103.23 ng/mL increased to 124.09 ± 78.01 ng/mL ($p < 0.05$) at one month and expressed an exaggerated postprandial response, followed by a fall in fasting level to 49.73 ± 56.11 ng/mL ($p = 0.169$) at six months (see Figure 1).

From these results, we infer that DJB-SG causes a decrease in ghrelin and an exaggerated incretin response. This leads to a decrease in hunger, increase in satiety and a better glucose control.

Figure 1. Measurement of C-peptide and hormone levels at zero, one and six months against time in minutes alongside an oral glucose tolerance test.

Advantages

A number of other advantages are noteworthy from DJB-SG. It allows screening of the stomach for gastric cancer, which is quite difficult to perform after RYGB [21-23]. This is especially beneficial for the high-risk populations. The anatomical preservation of the pylorus, being a physiologic valve, has several functions. It serves as a natural barrier for the gastric mucosa against pancreatic and biliary juices thereby preventing bile reflux gastritis [24]. It also regulates gastric emptying, leading to less occurrence of dumping syndrome. Likewise, more gastric size is preserved, improving the absorption of iron, calcium, vitamin B₁₂, and protein [23, 24].

Another advantage of DJB-SG is its versatility of conversion to another procedure as indicated, such as in cases of leaks or strictures. The LDJB-SG may be easily converted into DS by transecting of the afferent limb and anastomosing it to the efferent limb distally. In the RYDJB-SG, adjustment of the Y-limb to lengthen the Roux limb could convert it to DS. Transformation of the DJB-SG to RYGB is also feasible, by transecting the duodenojejunal anastomosis, resection of distal gastric tube and bringing up the alimentary limb for a gastrojejunal anastomosis.

When comparing with RYDJB-SG, a loop technique could display some advantages. The single anastomosis by loop fashion offers a reduced operative time and decreases potential complications from another anastomosis of the Roux-en-Y jejunostomy. Also, only a single mesenteric (Petersen) defect needs to be closed in a loop technique [24].

Marginal ulcer is also unreported in the loop technique, probably due to the immediate neutralization of the gastric acid by the bile upon entry into the duodenum.

THERAPEUTIC OUTCOMES

Earlier studies of DJB involving non-obese patients with diabetes showed some clinical improvement, including HbA_{1c} and fasting blood glucose over three months which remained controlled at one year. Decreased medication requirements were noted; although, the patients did not have a remission of diabetes [25, 26]. The procedures in these studies did not include an SG, which defines the postoperative weight loss being a strong predictive factor in diabetes remission. The effect on glucose metabolism however, is still multifactorial. Literature review reported up to 97% of morbidly obese SG patients had an improvement or resolution of T2DM at a mean of 13 months. Though, this drops to 60.8% at five years, with a 13% recurrence rate [27]. Combining LSG and DJB together should result in a synergistic weight loss and glycemic control.

The series by Kasama's group observed the weight loss and glucose metabolism effect of DJB-SG on the morbidly obese with associated diabetes. At one year, percent excess weight loss (EWL) was 99.4%, with 91% of subjects achieving glycemic control of HbA_{1c} below 7% at one month. A meal tolerance test conducted showed a significant reduction of glucose area under the curve (AUC) and an increase in insulin AUC at six months. Continuous glucose monitoring done on selected patients showed a dramatic response of glycemic control. The patients had decreasing insulin requirement on the first postoperative day, to no diabetic medication on the second postoperative day [22]. A preliminary study by Kasama et al. in 2009 involving 21 patients who underwent DJB-SG showed that short term percent excess BMI loss at one year was similar to their previous series of RYGB, and superior to LSG and gastric banding. Resolution of diabetes at 93% was also better than their series of LSG (67%). They likewise showed 100% and 85.7% resolution of hyperlipidemia and hypertension, respectively [14]. In 2012, Raj et al. randomized 57 morbidly obese patients to DJB-SG and RYGB. At one year, the BMI and percent EWL between the two procedures were not statistically significant. The remission rate for diabetes was similar at 80% and 81%, respectively. Resolution of hypertension and dyslipidemia was also similar between groups, with all subjects having 100% resolution of dyslipidemia [28]. A medium-term study of 120 obese patients with diabetes showed preoperative body weight and BMI to have decreased from 105.7 Kg and 38.5 Kg/m² to 74.9 Kg and 27.2 Kg/m² at one year respectively, and reached a plateau up to five years. Changes in HbA_{1c} and fasting blood glucose showed a drop from 8.9 to 6.0 and 194 to 105, respectively, at one year follow-up and maintained thereafter for five years. There was an improvement in OHA and insulin use by the first postoperative year and it continued for five years. The number of patients that were off medications increased from 5% to 86%; 48% using OHA decreased to 10%; 15% using insulin decreased to 1.8%; and 30% using both OHA and insulin decreased to 2.7%. The reported remission rate was at 63.6% [21].

In 2013 Huang et al. published a report on performing DJB-SG using a loop fashion in a lower BMI population with diabetes. At six months, the mean BMI of 28.4 dropped to 22.4, with 91% of the subjects achieving HbA_{1c} below 7.0 without medications [15]. Another study

by Lee et al. compared the LDJB-SG with SG alone. They reported LDJB-SG to have a better weight loss in lower BMI (23.9 versus 26.1) and more EWL (87.2% versus 67.5%) at one year. Diabetes remission rate was also higher with LDJB-SG at 93% versus SG at 87% [23]. A comparison with gastric bypass in the morbidly obese showed better weight loss in LDJB-SG with a drop of BMI from 38 to 25.9, and EWL at 80.3% versus BMI 27 and EWL 63.4%. However, LDJB-SG showed higher total cholesterol and low-density cholesterol levels compared to a gastric bypass [24]. In contrast, Huang et al. found no statistical difference in the outcomes between LDJB-SG and RYGB in diabetic patients with BMI less than 35 Kg/m². Weight loss reported a BMI drop in LDJB-SG from 28.2 to 22.4 versus RYGB at 27.8 to 21.9. The glycemic control of HbA_{1c} below 7 for LDJB-SG was at 73.3% versus RYGB at 63.3% [29].

INDICATIONS AND CONTRAINDICATIONS

DJB-SG can be used in the treatment of morbid obesity or obesity with T2DM [30].

Indications	
Body mass index (BMI) ≥ 35 Kg/m ² with co-morbidities or BMI ≥ 40 Kg/m ²	
Class III Obese	BMI > 40 Kg/m ² with DM
	BMI > 37.5 Kg/m ² with DM for Asians
Class II Obese	BMI 35kg - 39.9 Kg/m ² with DM
	BMI 32.5 - 37.4 Kg/m ² with DM for Asians
	Surgery is recommended if poor glycemic control
	Surgery may be considered if adequate glycemic control
Class I Obese	BMI 30-34.9 Kg/m ² with poor glycemic control
	BMI 27.5-32.4 Kg/m ² with poor glycemic control for Asians
Overweight	BMI < 27.5 Kg/m ² in experimental cases with informed consent
Absolute Contraindications	
Psychiatric illness: active psychosis, purgative behaviors, untreated or undertreated psychopathology and medical nonadherence	
Drug abuse/alcohol abuse	
Relative contraindications	
Type 1 DM	
C-peptide <1	
Duodenal ulcer	
Severe GERD (Grade C and D)	
Barretts' esophagus	
Bile reflux gastritis	
Chronic pancreatitis	

PROCEDURE

Preoperative Considerations

A comprehensive, multidisciplinary bariatric management program is utilized for the preoperative preparation and postoperative management of patients. The program should

include a support group and ancillary personnel to help provide nutritional information, psychological care and an exercise program. Prior to the operation, patients are assessed by a multidisciplinary team which includes a surgeon, endocrinologist, anesthesiologist, psychiatrist, and dietician. Every patient undergoes a routine preoperative work-up and counseling. Esophagogastroduodenoscopy is consistently performed to screen for neoplasm, peptic ulcer, reflux esophagitis, hiatal hernia, and *H. pylori* infection. Smokers are additionally sent for smoking cessation counseling [29].

Patients are admitted one day prior to their scheduled surgery to stabilize the blood glucose level to less than 200 mg/dL, with a continuous insulin infusion as necessary. All patients are instructed to be on a clear liquid diet at admission [31]. A single dose of cephalosporin and pantoprazole are given half an hour prior to the start of the surgery. Antithrombotic devices and low molecular weight heparin are both prescribed to prevent deep venous thrombosis and thromboembolic events.

Duodenojejunal Bypass and Sleeve Gastrectomy Operative Technique

The addition of DJB to SG makes the procedure more technically challenging, translating to longer operative times and a longer hospital stay duration compared to RYGB or LSG alone. The identification of important landmarks, performing certain maneuvers, and careful manipulation of structures makes the procedure more time consuming. Some advancement in laparoscopic skills are required to perform adequate duodenal dissection and transection, as well as a watertight anastomosis to complete a safe and successful surgery. The addition of another entero-entero anastomosis in the Roux-en-Y technique, and the necessary closure of mesenteric defects to avoid future internal herniation also contributes to the added operative time. Although there is more intraabdominal manipulation involved, blood loss should be almost similar to LSG at minimal amounts in an uneventful procedure. However, the surgeon must be mindful in troubleshooting during inadvertent circumstances.

Roux-en-Y Technique

After general anesthesia, the patient is placed on supine position with legs separated. Five ports are used in this procedure. The laparoscope port is placed at the supra-umbilicus and a 5 mm port is placed at the sub-xiphoid space for liver retraction. Two 12 mm ports are then placed at the left subcostal margin and a 10 mm port caudal from the left subcostal margin. A 15 mm blade port is placed at the right upper abdomen for specimen retrieval.

Sleeve gastrectomy is performed with a 36 Fr bougie using linear staplers starting at 4 cm from the pylorus. Sutures over-sewing the staple line are added at the remnant stomach to prevent leakage and bleeding. The posterior wall of the duodenum is carefully dissected and devascularized. The duodenum is then divided with a 60 mm endoscopic linear stapler Endo GIA curved tip with tri-staple™ (Covidien, USA) at 1-2 cm distal to the pylorus. The biliopancreatic limb is measured 50-100 cm from the ligament of Treitz and divided with a white cartridge linear stapler. The total alimentary tract is measured to 150-200 cm and a linear stapler is used to create the jejunojejunostomy. The entry hole of the jejunosjejunostomy and mesenteric defect are closed by hand-sewn technique. Division of the

omentum is done to help avoid tension on the anastomosis in an antecolic reconstruction. Two layers of running sutures with absorbable material are then used to create the duodenojejunal end-to-side anastomosis [14, 21, 22].

Figure 2. Schematic diagram of the Roux-en-Y technique.

Figure 3. Completed anastomosis of the duodenum to the Roux limb of jejunum.

Loop Technique

The patient is placed on a supine position with abducted arms after initiation of general anesthesia. Five ports are used. Two 12 mm ports are placed at either side of the umbilicus at the midclavicular line. The left port is used for the laparoscope. A 15 mm port is placed at the umbilicus, and two 5 mm ports are placed at both subcostal margins.

Either a Nathanson liver retractor or T-shaped liver suspension tapes can be used to retract the liver to give a good exposure of both the stomach and the duodenum. Sleeve gastrectomy is done over a 38 Fr bougie using a linear stapler beginning at 4 cm proximal to the pyloric ring. A tunnel is then created posterior to the first part of duodenum at 2 cm distal to the pylorus using a Goldfinger dissector (Ethicon Endo Surgery, USA) without devascularization of the duodenum. Transection of the duodenum is performed using the Endo GIA TM 45 mm Curved Tip Articulating Vascular/Medium Reload with Tri-Staple™ (Covidien, USA). The jejunum is measured at 200-300 cm from the ligament of Treitz. A 1.5 cm enterotomy is then created on the jejunum and the first part of the duodenum. A totally hand-sewn side-to-side anastomosis is created using a 3/0 absorbable suture. An anti-torsion suture is placed between the stomach antrum and the jejunum 4 cm proximal from the duodenojejunosomy. The Petersen's defect is repaired with a continuous non-absorbable suture and a Jackson-Pratt drain is placed behind the duodenojejunosomy up to the SG at the end of the operation [15].

Pearls

Identification of anatomical relationships is important to guide dissection and avoid inadvertent injury to nearby structures. Before doing transection, the common bile duct must be identified. This runs vertically down behind the first part of the duodenum and lies to the right of the gastroduodenal artery serving to label the junction between the first and second portion of the duodenum. Careful and clear dissection of the duodenum off the pancreas should be done with extreme caution to avoid its injury and bleeding due to the multiple small vasculatures and proximity of the gastroduodenal artery. An addition of a traction suture at the antrum of the gastric tube to pull the stomach laterally allows countertraction of the duodenum, facilitating its dissection, as well as, avoiding excessive manipulation of the duodenum and risking injury to its wall and vasculature. In super obese patients where there is abundant periduodenal fat thus rendering difficulty in dissecting a tunnel below the duodenum, it may be necessary to sacrifice the right gastroepiploic vessels. Once a tunnel is fully dissected between the duodenum and pancreas using a Goldfinger dissector (see Figure 6), a vascular tape may be inserted and used to lift the duodenum during insertion of the stapler (see Figures 7 and 8). Using a curved tipped stapler allows easier passage through the created tunnel for the transection of the duodenum (see Figure 9). Special care must be taken not to injure the common bile duct, pancreas and major vessels surrounding the first part of duodenum.

Duodenojejunal anastomosis may be done in an end-to-side or side-to-side fashion. An end-to-side anastomosis may require some devascularization of the posterior aspect of the transected duodenum. A side-to-side anastomosis at 1cm distal to the pylorus is important to avoid its injury. This is also prevented by using a temporary stay suture over the pylorus and proximal jejunum, which also facilitates the hand-sewn anastomosis. Using a linear or circular stapler for anastomosis may risk injury to the pylorus. The Roux-en-Y techniques also includes another entero-entero anastomosis adding to the operative time. In the loop technique, where only a single anastomosis is done, an anti-torsion suture anchors the proximal jejunum to the stomach to prevent torsion or kinking of the jejunal limbs. Closure of Petersen and mesentery defects is necessary to avoid future potential internal herniation.

Postoperative Care and Follow-Up

Upon completion of the operation, extubation, and recovery from anesthesia effects, patients are then transferred to the surgical ward. Deep breathing exercises and early mobilization are encouraged for postoperative pulmonary care. Opioid analgesics are used for pain control. Clear liquid diet is initiated once the patient regains full consciousness. Patients can usually be discharged three days after surgery once they are able to tolerate oral fluids and pass flatus with no evidence of tachycardia.

A follow-up visit is scheduled at the outpatient clinic one week after discharge. Diet progression is continued as any routine bariatric diet. Medications for diabetes are adjusted accordingly based on close monitoring of the fasting plasma glucose (FPG) level. All patients may be given prophylactic proton pump inhibitors [29].

Subsequent follow-ups are carried out at one, three, six, nine and 12 months after the operation. The nutritional status of the patient must be reviewed by a dietician at every follow-up. Weight, blood pressure, FPG, HbA_{1c}, and C-peptide levels should also be documented.

Pitfalls

This procedure presents some disadvantages. It is important to note that the DJB-SG is irreversible. Long-term data are necessary to evaluate if it can replace RYGB as the gold standard bariatric procedure. In addition, this procedure might not be appropriate for less skilled surgeons or super obese patients because of the technical challenge involved, as reflected by the long operative time.

As performing a DJB may require some manipulation on the duodenum during dissection, inexperienced surgeons may cause inadvertent harm to the duodenal wall. Damage proximal to the transection may be remedied with the duodenojejunal anastomosis. However, a duodenal injury distal to the transection may cause a possible leak if it is not adequately repaired.

A common scenario encountered during a DJB procedure includes some bleeding after the transection of the duodenum. This may range from bothersome oozing from small multiple branching vessels, to a potentially disastrous bleeding gastroduodenal artery. Oozing may be controlled with hemostatic agents or by packing with gauze until adequate hemostasis has been achieved. Further manipulation may result in more tissue injury and worsen the hemorrhage. A damaged gastroduodenal artery resulting to torrential bleeding would require either a suture repair or ligation, or even conversion to an open laparotomy as necessary.

Injury to the common bile duct during dissection may occur if duodenal transection was done too distally and close to the second duodenum. Avulsions and small duct lacerations should be repaired primarily with a T-tube limb passed through the repair. However, a complete transection may call for a complete biliary reconstruction.

Another disadvantage in transecting the first part of the duodenum is the preclusion of endoscopic modalities to approach the Ampulla of Vater for management of patients who develop complicated choledocholithiasis and biliary obstruction. Hence, patients found to have cholelithiasis preoperatively are offered to undergo concomitant cholecystectomy during

the index surgery, or it may be offered as an elective procedure if cholelithiasis develops postoperatively, even without symptoms.

COMPLICATIONS

Hemorrhage

Incidence of bleeding from SG is reported to be at 1-6% [32], and 0.94% in RYGB [33] which may be intraluminal or intraperitoneal. Intraluminal bleeding may present as hematemesis or melena. This can be managed similarly for any other upper gastrointestinal bleed. Intraperitoneal bleeding may present as a serial drop in hemoglobin with signs of hypovolemic shock. This can be managed conservatively or by re-laparoscopy as necessary according to the patient's condition [22]. Patients' presentation may range from asymptomatic to tachycardia with impending hypovolemic shock. Potential sources of hemorrhage could be from the trocar site, staple lines, duodenal bed, anastomotic sites, or iatrogenic injuries to the surrounding structures [21-23, 33]. Resuscitation and re-laparoscopy is imperative if the patient begins to show signs of hypovolemic shock. This allows immediate diagnosis, evacuation of hemoperitoneum, identification and control of the bleeding source.

Leak

Leak is a dreaded complication where peritonitis and sepsis can potentially lead to morbidity and mortality. The leak may occur either at the staple line or at the anastomosis. The incidence of leaks from a gastric staple line and enteric anastomosis occurs up to 5% [32]. The patient may present with signs of a systemic inflammatory response syndrome, abdominal pain, nausea, vomiting, and an altered mental status. A combination of fever, tachycardia and tachypnea is 58% sensitive and 99% specific for detecting a leak [34]. Diagnosis in the early postoperative period necessitates immediate re-exploration, peritoneal toilette, and primary repair if tissue viability would permit. Management of late leaks may allow the liberty of a conservative approach depending on the patient's clinical condition. This includes adequate resuscitation, drainage of abscess and use of an endoscopic stent in a gastric leak [32]. A duodenojejunal anastomotic leak would warrant a reoperation with conversion to a Roux-en-Y configuration or into RYGB with removal of the distal stomach and the first part of the duodenum [15].

Sleeve Gastrectomy Related Complications

Gastroesophageal Reflux Disease

Most surgeons have agreed that SG should be contraindicated to patients with severe gastroesophageal reflux disease and Barrett's esophagus [35]. The prevalence of erosive esophagitis and reflux symptoms increase after undergoing SG with a de novo incidence of 23% at one year [36, 37]. Reported in DJB-SG series are from 30% to 65% esophagitis and

20% new occurrence of reflux symptoms [29]. Although these symptoms may be treated with proton-pump inhibitors, close clinical follow-up is necessary to monitor for progression of the disease. Braghetto et al. followed 231 patients after SG and reported Barrett's esophagus at 1.2% occurring at three to five years after surgery [36]. Conversion to RYGB may be another option for progressive or intractable reflux symptoms.

Gastric Tube Stricture

The reported incidence of gastric sleeve stricture in DJB-SG series is around 2.5%, [21-23, 28]. Symptoms may present early due to tissue edema or kinking of the gastric tube, and may be managed conservatively with intravenous hydration and bowel rest. It can also have a delayed presentation with the most common site of stricture at the incisura angularis. Short segment strictures may be managed with endoscopic dilatation. Longer segment strictures would require laparoscopic seromyotomy [32]. Conversion to RYGB may be another option after failure of seromyotomy [22, 23].

Duodenojejunal Bypass Related Complications

Internal Hernia

Internal hernias would present with signs and symptoms of abdominal pain, bowel obstruction or gangrene. Physical examination and an imaging modality may facilitate diagnosis. Internal hernias may occur either at the Petersen or mesenteric defect. Incidence is reported to be at less than 1% in RYDJB-SG series [21, 28]. Although the incidence is low, closure of the defects prevents potential internal hernia. This may be complicated by ischemia and necrosis in 7-42%, and increasing associated mortality [39]. A trocar site hernia may occur in open fascial defects of greater than 10mm or if dilatation was done to facilitate extraction of the gastric specimen [40].

Marginal Ulcers

Marginal ulcer is a potentially serious complication of the gastrojejunal anastomosis, and may progress into complications of bleeding, perforation, or stenosis. It has been reported to occur up to 12% after RYGB [41], contrary to being nearly unreported in duodenal switch and SADI-S [13, 42, 43]. The series by Huang et al. reported no incidence of marginal ulcer after LDJB-SG [29], whereas Seki et al. has reported minimal incidence at 0.49% of RYDJB-SG [21]. The presence of the pylorus may play a role as a protective barrier. The loop technique likewise allows alkaline juice to immediately neutralize the gastric acid in the anastomosis site. In contrast, the Roux-en-Y fashion technique still renders direct contact of the gastric acid to the intestinal mucosa.

Dumping Syndrome

Changes in the digestive anatomy and glucose metabolism resulting to dumping syndrome may become debilitating for the patients occurring at 15-76% after RYGB. However, this is not reported after duodenal switch [42, 43]. The preservation of the pylorus

allows a more delayed and regulated gastric emptying. The series by Kasama et al. reported only 4% of subjects having symptoms that were suggestive of dumping syndrome including abdominal pain, fatigue, facial flushing, perspiration tachycardia, and hypoglycemia [3].

Malnutrition

To date, there has not been any literature focusing on the nutritional aspect of DJB-SG. The series by Lee et al. in 2014 and 2015 compared the nutritional status of DJB-SG to SG alone, showing no difference of nutritional status at one year after surgery. This is possibly also due to the pyloric preservation which prevents dumping syndrome. Preservation of acid and intrinsic factors also facilitates more absorption of iron, calcium, vitamin B12 and protein [23, 24]. At the present time, DJB-SG follows the same vitamin supplementation guidelines as for RYGB. A more prospective study is needed to determine how DJB-SG will affect nutritional deficiency.

CONCLUSION

Loop and Roux-en-Y DJB-SG both show promising results in the treatment of morbid obesity and obesity with T2DM in the Asian population. DJB-SG is at least comparable to other bariatric procedures but with less adverse effects. Hence it could be considered as an alternative option. However, more studies are needed to evaluate the long-term outcomes of diabetes remission and nutritional consequences. Furthermore, these studies are expected to test the applicability and outcome for the Western population.

ABSTRACT

As reported by the last IFSO worldwide survey on bariatric surgery, sleeve gastrectomy became the second most performed bariatric/metabolic procedure in the world just after gastric bypass.

Sleeve gastrectomy had a wide diffusion probably due to the easy surgical technique, although it must not be considered safe from complications, which can be severe and even life-threatening. Technical tips, and standardization of the procedure are required in order to minimize complications such as gastric leaks, stenosis and bleeding. To ensure high quality standard of this surgical treatment, dissection and resection should be done using appropriate technology.

The aim of this review is to present various technical aspects and tips reported in literature in order to optimize the surgical procedure in safety and effectiveness. In particular we focused our attention to trocars positioning, dissection of the greater curvature, dissection of the angle of His, bougie caliber, application of the stapler and haemostasis.

INTRODUCTION

The last global survey of bariatric/metabolic surgery of the International Federation for the Surgery of Obesity and Metabolic Diseases (IFSO), published in 2015, showed an increase from 0% to 37% of sleeve gastrectomy procedures performed between 2003 and 2013 in all the considered geographical areas [1].

The diffusion of this obesity surgical treatment is encouraged by the easy surgical technique required and its standardization, supported by the effective short-term weight loss.

According to the literature, the worldwide diffusion of sleeve gastrectomy determined an increase of complication rate from 1% to 7% [2, 3].

The most relevant complications after sleeve gastrectomy are gastric leaks, bleeding and stenosis. Gastric leak is a challenging complication due to the possible consequences in terms of morbidity and mortality. In fact, gastric fistula may prolong hospital stay and may cause abdominal sepsis and multiple organ failure. Moreover this complication may require further surgical or endoscopic procedures.

Because of this serious complication it is rightful to ask if sleeve gastrectomy is as an easy procedure as it is described. It is mandatory to point out the steps of the procedure in order to understand the critical technical and anatomical aspects.

Pneumoperitoneum

Pneumoperitoneum is not always an easy and uneventful procedure because of the thickness of the subcutaneous adipose component of the abdominal wall in obese patients, particularly in women.

There is no consensus about the pneumoperitoneum technique in sleeve gastrectomy. Three principally different techniques exist: initial pneumoperitoneum by Verres needle, open Hasson technique, and direct placement of an optical trocar with a 0° or 30° laparoscope. In a large nationwide survey dealing with Roux-en-Y gastric bypass (LRYGB), the most common way to perform pneumoperitoneum was the Veress needle technique before placing the first trocar (59%), followed by the optical trocar (30%), and the open Hasson technique (11%). The injuries were evenly distributed between the Veress technique and direct placement of an optical trocar, while no injuries occurred with the Hasson technique [4]. As suggested by Kassir et al. [5] the entry site of Veress needle is the Palmer's point, in the left subcostal margin on the midclavicular line.

Trocars Position

Trocars number and position are quite variable and not so standardizable as it changes with surgeon's experience and preference. Positioning trocars is still a controversial subject. Right placement of the trocars is essential for the ergonomic setting of the surgeon and for an effective approach to the angle of His. The best position of the first trocar is still controversial, as there is no evidence to support any particular technique. The correct fixed anatomical landmark in obese patients is not the umbilicus but the xiphoid process. The 12-

mm trocar on the patient's right side is important because the stapler for gastric resection is positioned from this trocar. As described by Ruiz de Angulo [6] the two first cartridges guide the rest of the gastric section. This trocar should not be placed too high in order to start resection on the antrum without excessive articulation of the stapler, oriented directly to the angle of His. On the other hand, this trocar must not be placed too low because it could be difficult to complete gastric resection upward to the angle of His without excessive tension.

Because of the thickness of the abdominal wall in the obese patients and the greater risk of trocar incisional hernia after weight loss, trocars must be positioned with an angle of 45° with the abdominal wall.

Bougie Size

Sizing the sleeve with calibrated oro-gastric bougie is mandatory. The bougie guides the stapling resection and helps to stay away from the incisura angularis and the gastro-esophageal junction (GEJ). The choice of the most suitable bougie is important in order to avoid stenosis and leak for too tight sleeve and failure in weight loss for too dilated sleeve. As stated by the international consensus summit and the international sleeve gastrectomy expert panel consensus, the optimal bougie size ranges from 32 to 36 F [7, 8]. The 36 F bougie is the most used.

Figure 1. Oro-gastric bougie positionment.

Greater Curvature Dissection

Greater curvature is mobilized and dissected from 5-10 cm proximal to the pylorus up to the angle of His. Dissection must preserve the antrum in order to maintain the antral pumping function, and, in the same time, it must be careful to avoid bleeding from the omental flap.

A complete mobilization of the fundus with the exposure of the left diaphragmatic pillar is of utmost importance. Posterior gastric wall should be fully mobilized through the section of the short gastric vessels and division of the adhesions to the pancreas. In this way anterior and posterior gastric walls are prepared symmetrically to allow optimal positioning of the

stapler, avoiding the twisting of the sleeve. The dissection of the GEJ should not be too extended in order to preserve its microvascular pattern and to avoid impairment of the hiatus and the phreno-esophageal membrane. An aggressive dissection of GEJ could predispose to the leak of the proximal third of the sleeve and to transhiatal herniation of the sleeve.

Several energy tools are used for the greater curvature dissection, such as ultrasound and radiofrequency devices. The best device should guarantee an optimal sealing effect both on the gastro-omental ligament and on the short gastric vessels, minimizing the bleeding of the omental flap. Devices must be suitable for an effective and fast dissection of thick tissues as the omentum in the obese patients. Moreover said instruments must to be suitable for gastro-splenic ligament dissection and safe control of the short gastric vessels.

Figure 2. Greater curvature dissection.

The risk of spleen lesions is particularly high in the greater curvature dissection, due to the gastric fundus at the His angle possibility to be redundant, and its proximity to the upper pole of the spleen.

The intraoperative investigation of hiatal hernia should be systematically performed, particularly if it is diagnosed by the preoperative endoscopy and/or the upper gastrointestinal swallow study; once hiatal hernia is found, it should be repaired.

Resection

The gastric transection using a flexible linear 60-mm stapler is performed after the positioning of the oro-gastric bougie along the lesser curvature. The surgeon inserts the stapler from the trocar in the right flank and starts the transection 5-6 cm from the pylorus, at the lower end of the crow's foot along the bougie.

The first firing of the stapler must be far from the incisura in order to avoid stenosis, twisting, and a possible concomitant gastric leak. The transection proceeds in a linear regular way towards the angle of His. During the stapling it is important to maintain a moderate symmetric lateral traction. Direction of the staple-line should be maintained along the lesser curvature with a correct use of the stapler. The last firing should stay 1-1.5 cm away from the GEJ in order to protect the distal part of the esophagus, avoiding stenosis and gastric leak.

Figure 3. Greater curvature dissection.

Figure 4. Short gastric vessels dissection.

Figure 5. Left diaphragmatic pillar exposure.

It is appropriate to modulate height firing according to the thickness of the gastric wall. In fact, staple mismatch is one of the causative factors of gastric leak after sleeve gastrectomy. The choice of the optimal height cartridge is a controversial topic: too high cartridges predispose to the bleeding of the staple-line but allow a rightful closing; too small cartridges may prevent an adequate sealing and predispose to leaks, particularly in case of stenotic or twisted sleeve or in case of redo surgery. Surgeons are implementing various measures to reduce these complications such as buttressing material, fibrin sealing, oversewing, and metal clips. Higher staple height should be used combined with buttress material in case of thicker and scarred stomach as occurred in redo surgery. The new powered technology of the flex staplers could be a further and appropriate tool to ensure a closer, safer and bloodless staple-line, thanks to its greater stability.

Leak Test

Staple-line leak is the most serious and challenging complication of sleeve gastrectomy. The reported incidence varies from 0% to 8%. The 80% of gastric leaks affect the upper third of the sleeve, below the GEJ. The main causes include high pressure of the gastric sleeve, stenosis of the incisura, sleeve twisting, direct damage or microvascular injury of the GEJ, excessive tension or misfiring of the stapler. Leaks after sleeve gastrectomy are classified as acute, early, late, and chronic. They can result in significant morbidity and mortality. Early diagnosis and treatment is important in the management of a leak. However, it can be treated safely via various management options, depending on the time of diagnosis and size of the leak. Intraoperative methylene blue and air leak tests are routinely used to evaluate for leak; however, there is minimal literature and consensus on the utility of these tests [9]. Some studies demonstrated that leak tests sensitivity is very low. Although intraoperative leak tests are very common, they are unable to detect a leak and do not impact on postoperative leak rate [10, 11, 12]. These intraoperative leak tests continue to be performed in the daily practice, even if they would serve the purpose only in selected cases, with evidence or high suspicion of stapler misfire.

Figure 6. Stapler firing during sleeve gastrectomy.

Figure 7. Stapler firing during sleeve gastrectomy.

Figure 8. Stapler firing during sleeve gastrectomy.

Figure 9. Stapler firing during sleeve gastrectomy.

Haemostasis

Haemorrhage is a recognised complication of bariatric surgery; it can compromise healing of staple-lines and anastomoses or result in abscesses with attendant risk of late staple-line leaks. The long stapler line is mostly responsible for postoperative bleeding (0%-20% of the cases) [8]. Other possible bleeding sites are the omentum, trocar sites, and iatrogenic injury of the liver or the spleen. Intraluminal bleeding is uncommon.

Figure 10. Application of sealant material on the staple-line.

Figure 11. Application of sealant material on the staple-line.

A meticulous haemostasis of the staple-line, the greater omentum and the trocar sites is essential. Dissection of the greater curvature must be accurately performed with the appropriate use of the energy device, in order to allow an effective clotting and sealing effect. The choice of the most suitable height firing of the staple-line contributes to minimize the bleeding. During the last years, several tools have been proposed to reinforce the staple-line and prevent staple-line bleeding such as oversewing, absorbable synthetic buttress material (synthetic glycolidtrimethylene carbonate copolymer Gore®Seamguard® Bioabsorbable

Staple Line Reinforcement), biologic cross-linked buttressing (Bovine pericardium strips, Peri-strips Dry[®] and PSD Veritas[®] Baxter), biologic absorbable non-cross-linked buttressing (porcine small intestinal submucosa, Surgisis Biodesign[®]), thrombin matrix (Floseal[®], Baxter) [13]. Several trials and reviews reported a reduced rate of bleeding with buttress materials, oversewing or use of sealing materials but without strong statistical differences [3, 14, 15]. The international consensus expert panels of sleeve gastrectomy reported that buttressing of staple-line is practiced by the majority of surgeons. Techniques of staple-line reinforcement could be also cost-effective particularly in patients with high risk of bleeding (antiaggregant or anticoagulant therapy).

DISCUSSION

Sleeve gastrectomy began to be used as first step procedure of a variation of biliopancreatic diversion with duodenal switch in super-obese, high-risk patients. Subsequently, thanks to the good results in safety and weight loss, sleeve gastrectomy was proposed as a single procedure. Recently it has become a common performed procedure with a consistent increase in the last years. In fact, it is the second most performed bariatric procedure after Roux-en-Y gastric bypass, as reported in the last IFSO survey. This gain of popularity, as described by Zellmer et al. [16], is due to the relative ease of the procedure, short operative time, and good outcome in terms of weight loss, comparable to gastric bypass. Whether the sleeve gastrectomy is really such an easy and an uneventful procedure is still a controversial topic. The procedure could be challenging especially in obese patients with BMI > 45-50 kg/m². The anatomical aspects which can influence complexity of the procedure and length of operating time include large gastric fundus, cascade gastric fundus, strict adhesions to the upper pole of the spleen.

Despite of a recent systematic review and meta-analysis reported a substantial decrease in sleeve gastrectomy complication rate [17, 18], leaks after sleeve gastrectomy still varies between 0% and 18% [19]. The wide diffusion of sleeve gastrectomy, even in low-volume centres, could lead to an underestimation of leak rate as the incidence reported in literature is usually related to high-volume centres and experienced surgeons. For this reason it is mandatory to keep national registers of sleeve gastrectomy procedures in order to collect realistic leak rate and overall complication rate.

To minimize surgeon-related risk factors, each step of the sleeve gastrectomy must be standardized. The International Consensus Summit represents a viable and effective resource, sharing an updated overview about preoperative and intraoperative aspects of sleeve gastrectomy.

Moreover each step of the procedure must be performed with a great attention to the detail, bleeding during dissection manoeuvre, excessive tension in the stapling procedures, choice of the more appropriate height cartridge to avoid bleeding and leak of the staple-line, choice of the most suitable haemostatic device and agents considering also the patient's risk factors for bleeding.

CONCLUSION

Sleeve gastrectomy is often defined as an easy bariatric procedure but still presents harmful complications, even life-threatening, and could be technically challenging in some cases. Only standardizing the procedures and carrying out meticulously each step of the operation, can be a viable and effective way to prevent and control the surgical complications. Attention to detail makes the difference.

ABSTRACT

Laparoscopy and minimally invasive surgery has continued to play an increasingly large role across all surgical fields including general surgery, gynecology, colorectal surgery, hepatobiliary surgery, and urology. By minimizing trauma to the abdominal wall, allowing faster recovery postoperatively, decreasing length of hospital stay, and improving cosmesis, laparoscopy has become the gold standard approach for many operations due to these improved outcomes. However, laparoscopic surgery demands its own unique set of surgical skills due to loss of tactile feedback, operating within a three-dimensional space as seen on a two-dimensional monitor, and the importance of recognizing spatial relationships. A learning curve is found to exist as one is further developing these skills. In order to further develop these skills prior to utilizing them in the operating room, live animal models and laparoscopic simulators have been developed. Live animal models including pigs, rabbits, and rats have been used for training, and it has been found that *in vivo* models appear to most closely resemble operating on patients; therefore, animal models are the ideal training model to be used in laparoscopic surgery training. As laparoscopy continues to become more popular throughout surgery, it also continues to evolve in order to further reduce the invasiveness of surgery as seen in robotic surgery, single incision laparoscopic surgery (SILS), and natural orifice transluminal endoscopic surgery (NOTES). These surgical techniques are the future of laparoscopic surgery and as their use becomes more widespread, training on experimental models specific to these methods will become even more important in order to optimize surgical outcomes for patients.

IMPORTANCE OF LAPAROSCOPIC TRAINING

Laparoscopic surgery requires a unique and at times more complex skill set than open surgery. In order to further develop these skills prior to utilizing them in the operating room, live animal models and laparoscopic simulators have been developed. Live animal models including pigs, rabbits, and rats have been used for training, and it has been found that *in vivo* models appear to most closely resemble operating on a live patient.

Laparoscopic surgery traces its roots to the early twentieth century when pioneers such as Dimitri Ott, Georg Kelling, and Hans Christian Jacobeus first began using laparoscopy as a diagnostic technique (Vecchio 2000). However, it was not until the early 1980s that a paradigm shift was made in the field of laparoscopy when laparoscopic procedures evolved from an invasive diagnostic tool to an efficient instrument for surgical treatment (Buia 2015). Over the last thirty years, laparoscopy has played an increasingly more predominant role across all surgical sub-specialties. As procedures become more complex and technically challenging, a need for additional robust laparoscopic skills training has been created. With ongoing improvements in surgical training, imaging, tools and instruments, laparoscopic surgery has been able to be safely used in innumerable fields. Additionally, experimental laparoscopic surgery helps to create a path for continuing evolution and new roles for laparoscopy to play in the future.

Laparoscopy has multiple advantages over open surgery such as minimizing trauma to the abdominal wall, which ultimately results in faster recovery, reduced hospital stay, and faster return to normal activity. As a result, laparoscopy has become the gold standard for many procedures despite lack of randomized controlled trials. Moreover, laparoscopy has been able to be used for oncological surgeries without providing inferior oncological results when compared to open surgery (Buia 2015).

Open appendectomy has been performed since the late 1800s with laparoscopic appendectomy gaining popularity during the 1980s. Meta-analyses comparing the two

procedures have indicated that while operating times were increased with open appendectomies, there was found to be shorter hospital stay, less postoperative pain, faster recovery, and lower complication rates found in the laparoscopic appendectomy group. Meta-analysis of randomized controlled trials comparing laparoscopic to open appendectomy have found that although operative time was shorter for the open procedure, laparoscopic surgery was associated with earlier consumption of liquid and solid diet, shorter hospital stay, decreased use of oral and parenteral analgesics, and decreased wound infection amongst several other advantages (Li 2010; Ohtani 2012).

Similar to appendectomy, open cholecystectomy initially was the gold standard for treatment of symptomatic cholelithiasis for over one hundred years. However, with the gaining prevalence of minimally invasive techniques, laparoscopic cholecystectomy gained prominence in the 1980s and allowed a greater liberalization of indications for surgery (Antoniou 2014). Meta-analyses comparing these two approaches have showed that while no significant differences were found between these approaches with regards to mortality, complication rates, and operative time, laparoscopic cholecystectomy is associated with significantly shorter hospital stay and quicker overall recovery (Keus 2006).

The benefits of laparoscopy can also be extended to anti-reflux and adrenal surgery. Open Nissen fundoplication during which the gastric fundus is wrapped around the distal esophagus has been used in treatment for moderate to severe gastroesophageal reflux disease since the 1950s, but the laparoscopic technique was not introduced until 1991 by Dallemagne (Memon 2015). It was hypothesized that the benefits of laparoscopic surgery including less post-operative pain, faster recovery time, improved cosmesis, and reduced rate of wound infection could also be conferred to laparoscopic anti-reflux surgery. However, initial studies demonstrated complications including esophageal and gastric perforation, paraesophageal herniation and wrap migration into the chest (Peters 2009). As experience with laparoscopic anti-reflux surgery has increased in addition to improved surgical techniques and training, the laparoscopic approach has proved to be a safe and effective alternative to an open technique in that laparoscopy allows a faster recovery, reduced risk of complications, and similar treatment outcomes between groups.

Despite the fact that minimally invasive surgery has facilitated improved surgical outcomes amongst various specialties, there are drawbacks to laparoscopy over open surgery. Work hour restrictions for residents, cost of operating room time, and increased learning curve for laparoscopic training creates the need for surgical trainees to acquire a large part of these skills outside of the operating room and in a more efficient manner (Roberts 2006; Trehan 2015; Alaker 2016). Furthermore, laparoscopic surgery requires a unique and at times more complex skill set than open surgery, which furthers the need for training facilities outside of the operating room in order for these skills to be further developed without putting the patient's safety at risk (Alaker 2016). In order to fill the need for additional training outside the operating room, surgical simulation has emerged as an opportunity to instruct surgical trainees on how to safely develop laparoscopic skills away from the time and financial constraints of the operating room. These simulators allow the issues of patient safety and risk management concerns to be addressed more efficiently and effectively while also helping trainees acquire skills needed to perform complex procedures before utilizing these skills on live patients (Roberts 2006).

LAPAROSCOPIC SURGERY LEARNING CURVE

Laparoscopy has continued to evolve over the last two decades, and this evolution has allowed it to gain a larger presence amongst many fields ranging from bariatric surgery to colorectal surgery to urology. As laparoscopic surgery has become increasingly more widespread as the method of choice for many procedures, this increased exposure has allowed surgeons across specialties to apply basic laparoscopic skills to more technically demanding surgeries. For both the novice and expert laparoscopic surgeon, a learning curve exists when learning how to perform basic and advanced tasks, respectively. Specific to laparoscopic surgery, laparoscopy requires a new, different skill set than what is required by open surgery. Laparoscopy can prove to be difficult to learn and is very different from open surgery due to loss of tactile perception, using a two-dimensional video screen to work within a three-dimensional space, spatial relationships, developing ambidextrous skills, and the fulcrum effect (Grantcharov 2009; Greco 2010; Buckley 2014). Due to these added challenges, a steeper learning curve exists within laparoscopic surgery when compared to open surgery, and it is during this phase that an increased incidence of serious complications may occur (Grantcharov 2009). As a result, it is imperative that trainees complete adequate training prior to operating on patients. In order to facilitate the teaching and assessment of trainees' fundamental knowledge and technical skills in laparoscopy, The Fundamentals of Laparoscopic Surgery (FLS) program was developed. The FLS curriculum consists of five simulation stations, which aim to teach and assess basic laparoscopic surgery skills: peg transfer, precision cutting, loop ligation, and suturing with extracorporeal and intracorporeal knot tying (Zendejas 2016). The FLS curriculum, which originally evolved from the McGill Inanimate System for Training and Evaluation of Laparoscopic Skills (MISTELS), also consists of web-based didactics, hands-on skills training and a written exam. Both the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) and the American College of Surgeons (ACS) have endorsed the FLS training program, which is now a prerequisite for board eligibility in general surgery. The FLS program has been found to be effective in regards to training; however, fewer studies exist which further explore the validity of the assessment component of FLS (Fried 2004).

Acquisition of skill in both laparoscopic and open surgery by trainees has been described in the literature as a "learning curve". The learning curve can be defined as the observation that repetitive performance of motor skills results in improvement over time. This improvement is most notable early on with sequentially smaller improvements as the number of repetitions increase (Feldman 2009). The learning curve can be divided into three main parameters: the starting point, the learning rate, and learning plateau. The starting point is the skill level at which performance begins. It is at the starting point and early portion of the curve that higher incidence of complications, increased rates of conversion to laparoscopic to open, and longer operating times are seen to be experienced. The learning rate is the slope along the curve which is measured by how quickly a level of performance is reached, and the learning plateau is the plateau or asymptote level at which performance flattens and no longer improves (Cook 2007). When applied to surgical skills, learning curves vary between surgeons and are influenced by multiple factors including a surgeon's innate ability, previous experience, motivation, available technology, task complexity, case-mix and operative findings, and other members of the surgical team (Cook 2004; Sachdeva 2007). In

applications to surgery, identifying where a trainee's skill level is located on their own learning curve can help to predict whether or not the trainee's skills will continue to improve. Traditionally, learning curves have been statistically analyzed by dividing the curve into halves or thirds with subsequent comparison of outcomes between earlier and later time periods. Although this approach may be useful for quantifying improvements over a period of time, it does not describe the underlying curve itself and does not allow for precise estimation of where the curve flattens and at what level this occurs. Furthermore, it does not allow for the estimation of individual skill differences between surgeons (Feldman 2009). By fitting an inverse curve to the performance curve of trainees, the learning curve effect can be estimated including the starting point, speed of learning, and plateau. Although not calculated on a regular basis amongst trainees, this technique may have a role in laparoscopic simulation when comparing groups of trainees who have been exposed to different educational interventions (Feldman 2009).

Although it has been shown that laparoscopic simulation helps trainees progress along the learning curve, some trainees possess an aptitude for laparoscopic skills which others may lack. This innate ability may allow for others to progress more quickly along the learning curve, and conversely, a lack of ability may prevent others from achieving adequate laparoscopic skills. In a study which examined this hypothesis, two groups of medical students with disparate innate ability were selected. Innate ability was defined as exceptional visuospatial ability, depth perception and psychomotor ability as measured by validated tests. Each group was tested on a laparoscopic skill trainer until they achieved proficiency in performing a laparoscopic appendectomy. The mean number of attempts to complete the procedure for the more skilled group was six attempts versus fourteen in the less skilled group. Furthermore, three participants in the less skilled group did not reach proficiency after eighteen attempts. This study demonstrated that high innate ability is directly related to a faster learning curve in achieving proficiency for a laparoscopic task (Buckley).

Aptitude testing can further be applied to more difficult laparoscopic skills such as laparoscopic suturing and intracorporeal knot tying. As indicated in previously mentioned studies, aptitude can be used to predict the rate at which a trainee is able to become proficient at basic skills. In turn, one's aptitude can also be used to predict how quickly one is able to achieve proficiency at more complex laparoscopic procedures. Students in the high aptitude group were found to have higher visual spatial, perceptual and psychomotor ability than those in the low aptitude group. After didactic teaching on how to perform laparoscopic suturing, students in each group were asked to perform this task. Figure 1 compares path length, economy of movement, and time scores between surgical novices with low or high aptitude. Group A achieved proficiency faster than group B. In the low-aptitude group, 30% achieved proficiency after a mean attempt of fourteen while 40% demonstrated improvement but did not achieve proficiency over the course of sixteen attempts; 30% failed to progress altogether and were unable to progress along the learning curve as seen in Figure 1.1B. Group A achieved proficiency in a shorter amount of time in both economy of movement and time scores as shown in Figure 3C and 1E, respectively. Figures 1D and 1F demonstrate the results seen in group B: 30% reached proficiency, 40% showed improvement but did not reach proficiency, and 30% failed to progress. Figure 1 demonstrates the mean number of attempts to achieve proficiency. For group A the average was seven (range, 4–10) in comparison to group B who required on average fourteen attempts (range, 10–16). In group B, 30% failed to progress and dropped out of the study. From this study, it can be concluded that distinct

learning curves based on innate ability also exist for technically more challenging tasks such as laparoscopic suturing. A significant proportion of those with lower aptitude were unable to achieve proficiency, which brings up the question of whether or not aptitude should be used to select surgical trainees. However, these tasks were performed in a simulated environment; therefore, it is unclear whether or not these skills would be transferrable to the operating room (Buckley 2014).

Figure 1. (A) Comparison of path length scores in surgical novices and (B) path length scores for all attempts in those with low aptitude. (C) Comparison of economy of movement scores in surgical novices and (D) economy of movement scores for all attempts in those with low aptitude. (E) Comparison of time scores in surgical novices and (F) time scores for all attempts in those with low aptitude.

Although it has been established that separate learning curves exist for those with and without an innate aptitude for laparoscopy, it is important to further delineate what makes this distinction between groups and whether or not this discrepancy is surmountable. Visual-spatial ability is thought to play a large role in achieving proficiency in both open and laparoscopic procedures. A group of thirty-seven surgical residents were asked to complete six tests in order to assess visual-spatial ability. After these tests were completed, residents were then asked to complete a Z-plasty procedure. This procedure consists of one or more Z-shaped incisions being made with the diagonals forming one straight line and two triangular sections, which is used for cosmetic reasons or can be functional in order to elongate and relax scars. Residents with higher visual-spatial scores performed better in the Z-plasty procedure in comparison to those with lower scores. However, after additional practice, residents with lower scores were also able to achieve competency (Wanzel 2002). This finding suggests that despite the fact that learning curves differed between the groups, additional practice and feedback may be able to make up for the innate differences between groups. In a separate study that examined visual-spatial ability and manual dexterity among dental students, surgical residents, and staff surgeons, it was found that higher visual-spatial ability scores were associated with a more skilled performance among surgical novices. However, superior visual-spatial ability among the more advanced trainees and experts was not found to correlate with superior performance on procedures. Therefore, these findings suggest that although aptitude testing may not be able to be used to predict who will perform well in a surgical career; however, it may be able to predict who would likely benefit from additional surgical training prior to entering the operating room (Wanzel 2003).

As previously stated, it has been established that laparoscopic procedures are associated with a learning phase during which there is an increased prevalence of serious complications. The learning curve for laparoscopic procedures is typically based on the time to procedure completion and the number of complications; however, multiple factors play a role in complications in the operating room in addition to surgeon experience such as the entire team involved in patient care at that time. In addition to describing time to proficiency, learning curve patterns may potentially also be used to identify surgical trainees who will be unable to achieve proficiency despite additional training (Grantcharov 2004). A virtual-reality trainer was used to measure the following parameters which has previously been validated in studies: time to complete task, number of errors, and economy of motion score (Taffinder 1998). Figure 2 shows the four learning curves that were identified: surgeons who (1) demonstrated proficiency from the beginning of the learning session (5.4%); (2) advanced with practice and achieved predefined expert criteria between two and nine repetitions (70.3%); (3) slow and steady acquisition of skills but unable to achieve proficiency level within ten repetitions (16.2%); and (4) underperformed from the beginning and showed no tendency to skills improvement (8.1%) (Grantcharov 2009; Kramp 2016). Trainees in the first group demonstrated impressive innate ability, potentially indicating a strong future in minimally invasive surgery; whereas those in the fourth group not only did not demonstrate any aptitude for laparoscopic surgery at the beginning, but they also failed to show any progression towards achieving proficiency. Although the role of surgeon involves skills such as communication and strong clinical judgment, technical skills play a large role. Therefore, one's performance on laparoscopic trainers should not be viewed in isolation; however, technical performance should be taken into consideration in order to help determine one's success in pursuing a surgical career (Grantcharov 2009).

Source: Grantcharov, T.P. and P. Funch-Jensen, Can everyone achieve proficiency with the laparoscopic technique? Learning curve patterns in technical skills acquisition. *The American Journal of Surgery*, 2009. 197(4): p. 447-449.

Figure 2. Learning curves. Time to perform the task. (a) Error scores. (b) Economy-of-motion scores. (c) Dotted line indicates the proficiency level for each parameter.

In addition to visual-spatial ability, several other cognitive abilities can be assessed in order to more completely understand one's aptitude in laparoscopy. A cognitive aptitude test may be used to assess trainees prior to laparoscopic simulator training. Ultimately, a surgeon's cognitive aptitude is related to the learning curve for minimally invasive surgery and the possibility of success in achieving proficiency (Luursema 2010; Luursema 2012). Spatial memory describes the ability to record information about one's environment and its spatial orientation. It can be viewed as an indicator of one's ability to learn the procedural aspects of tasks. Spatial memory is also related to the early learning phase of basic laparoscopic tasks (Luursema 2010). Perceptual speed is the ability to quickly identify a given shape or dissimilar shape from a number of alternatives. It is related to efficiency of movement in early learning, and it is also related to the associative phase of learning, which indicates that part of laparoscopic tasks might become automated during training. The fourth element of cognitive ability is reasoning ability. Increases in perceptual speed, a skill crucial due to the time critical nature of laparoscopic surgery, are found to be related to improved laparoscopic performance. The fourth element, reasoning ability, was found to be related to early learning of laparoscopic procedures. Reasoning ability was found to be less of an influence as skill level increased (Keehner 2006).

Since laparoscopic surgery requires a different mental skill set, it should be expected that the cognitive abilities of visual-spatial ability, spatial memory, perceptual speed, and reasoning ability should predict the learning curve for basic tasks on a laparoscopic simulator.

Laparoscopic surgery requires each of these skills; therefore trainees who perform exceedingly well on cognitive aptitude tests are expected to show high levels of performance in the following areas: (1) number of practice sessions in order to achieve proficiency; (2) time to task completion; (3) damage to surrounding tissue; (4) efficiency of movement on basic laparoscopic simulator tasks. Despite these expectations, cognitive aptitude was found to neither be related to total number of sessions required to achieve proficiency in a task, nor did it predict learning rate during training. Participants with lower cognitive aptitude scores were not found to require more practice sessions to reach proficiency in comparison to those with higher scores. Although trainees became quicker and more efficient in performing basic laparoscopic tasks on a simulator, damage to surrounding tissue remained constant. Cognitive aptitude did not affect the amount of tissue damage that was found. Although learning rates for trainees with discrepancies between their cognitive aptitude scores were similar, trainees with higher levels of cognitive aptitude were found to consistently outperform those with lower levels. Overall, there was no effect of cognitive aptitude on the learning curve across multiple sessions (Groenier 2014).

All four aspects of cognitive aptitude were associated with higher efficiency of movement. Visual-spatial and reasoning ability were associated with less time to complete a given task. The role of cognitive aptitude did change, however, when the influence of a cognitive ability was corrected for the effect of the other cognitive abilities. Perceptual speed remained positively associated with efficiency of movement; spatial memory and perceptual speed were associated with the amount of tissue damage.

ANIMAL MODELS OF LAPAROSCOPIC SURGERY TRAINING

Operating skills can be acquired via three methods, all of which have benefits and drawbacks. The first method involves the use of bench models, for which benefits include lower cost, ready availability, and reuse of materials (Martin 1997). Basic laparoscopy skills may be learned and further honed on trainer boxes or with virtual reality models, but as the trainee becomes more skilled, the need for more challenging and life-like models is required for skills to be further developed. As a result, animal models have become a popular way to simulate procedures in the operating room. The porcine model is the most commonly used model due to the pig's anatomical and physiological similarities to humans (Kobayashi 2012). The second method involves practicing of skills in the animal laboratory. The animal model represents an important step in the training process due to the fact that the direct step from the pelvic trainer model to the operating room may be too difficult for a trainee. The animal model also allows trainees to gain confidence in trocar use and positioning (Piechaud 2006). Although this method is expensive and also presents the issue of limited resources and funding, the use of animals very closely simulates operating on actual patients. The cadaver as a model also offers a very effective way to gain an understanding of anatomy through a laparoscopic view. Cadavers also provide macroscopic anatomy and improved spatial perception of anatomy. However, cadavers present certain disadvantages due to the fact that they do not bleed, the visual field is also clear, and no hemostasis can be done (Piechaud 2006). The third method takes place in the operating room under the supervision of a preceptor where trainees can gain real life experience. The drawback to this method is that

this can potentially be a dangerous situation in which trainees are further developing their skills on real patients. Training in the operating room is also limited by the fact that time and financial constraints limit the ability for trainees to perfect their skills here.

As more complex procedures are now being performed with laparoscopy in addition to shortened residency work hours, the need for intensive, efficient laparoscopy training is necessary for novices. This training can be conducted in a safe, controlled, and standardized environment within a simulation center; however, limited access to training centers does not always make this training possible. In order to provide additional training to general surgeons and graduating surgical residents, intensive training programs have been developed throughout the country as an alternative to simulation centers. Most intensive training programs are set up at locations throughout the country where general surgeons, residents, and fellows can travel to in order to complete an intensive training program over the course of several days. Intensive training programs may consist of lectures, laparoscopic videos, and practical training either on animal training models or laparoscopic trainers. Skill improvement is assessed using objective structured assessment of technical skill (OSATS). Most participants are found to have an improvement in their overall performance after finishing these courses (Castillo 2015).

For those that have access to simulation centers at their local institutions, there are numerous methods that can be used for preclinical training including virtual reality, box trainer simulators, operations on cadavers, or animal models. Although virtual reality or box trainer simulators have been used successfully by beginning trainees to acquire skills, they may be too simple and do not correlate closely enough to the actual procedure in the operating room. Therefore, human cadaveric and animal models have been introduced for more real-to-life training. Animal models have been found to be the ideal model due their realistic anatomy and surgical workflow similar to humans. Animal models are also ideal because they allow pathological findings such as cholelithiasis and inflammatory findings to be present, which is not possible in virtual reality or cadaveric models. Animal models are needed for two purposes. First, they allow new, minimally invasive procedures to be evaluated for their feasibility and effectiveness in comparison to standard techniques. Secondly, animal models provide training that most accurately resembles operating on real patients; therefore, it may also be used for training of both conventional and new methods of laparoscopic surgery (Ryska 2016). Due to both of these considerations, animal models are used throughout multiple surgical sub-specialties for preclinical training.

HEPATOBILIARY SURGERY

Training in laparoscopic hepatobiliary surgery with animal models has not gained large traction internationally due in part to its level of difficulty; however, success has been found when using the porcine model for training. Several differences exist between human and porcine liver anatomy, which can present a challenge to new trainees, but with the appropriate amount of preoperative preparation, the porcine model can offer a very realistic training model for laparoscopic liver surgery (Figures 3–6) (Martins 2013). Bovine and porcine livers are most frequently used due to their similarity to human livers in terms of size and density. These animals are also farm animals that are readily available and relatively inexpensive

(Ong 2013). The porcine liver has three hepatic ducts (left, right and middle) and join to form the common hepatic duct at the hepatic porta. The cystic duct is relatively long prior to joining the common hepatic duct, which also makes the porcine model a good model for laparoscopic cholecystectomy. The hepatic vein and inferior vena cava (IVC) confluence is intraparenchymal in pigs, which makes this dissection more challenging than in humans.

The IVC and intraparenchymal hepatic veins have extremely thin walls and the nearby diaphragm is easily damaged. Although external morphology of the porcine liver differs from the human liver, the segmental anatomy in regards to its vascularity and biliary tree is very similar to the human liver. Novice trainees were able to successfully perform Pringle maneuvers, left lateral segmentectomy and division of the liver ligaments. With appropriate preparation, the porcine model appears to be an adequate model for laparoscopic hepatobiliary surgery (Komorowski 2015). In other studies, laparoscopic left hepatectomy was successfully completed using a four-portal technique without the use of specialized instruments such as a LigaSure device, which further helps to decrease operative cost as seen in Figures 5, 6, 7, 8, and 9. This procedure offers a safe, feasible technique for laparoscopic left hepatectomy in pigs, which could additionally serve as a useful model for investigating liver disease, regeneration and offer preclinical information in order to improve hepatobiliary surgical procedures (Zhang 2014). Dogs have also been used in animal models to help surgeons further develop technical skills necessary to perform laparoscopic common bile duct

exploration. Previously it has been difficult to find a suitable animal model that possesses a bile duct diameter large enough to accommodate a fiber optic choledochoscope required for stone extraction. The dog model has been found to be an effective and reliable model, which will allow surgeons to not only further hone skills but to also develop new techniques in laparoscopic bile duct exploration (Crist 1994).

COLORECTAL SURGERY

Laparoscopy has been prevalent in colorectal surgery for many years at this point in time. New advances are being made within this sub-specialty with techniques such as natural orifice transluminal endoscopic surgery (NOTES). NOTES is an emerging technique that combines both endoscopic and laparoscopic approaches and uses natural body orifices as an entry site to the peritoneal cavity. This technique has already been applied to cholecystectomy and appendectomy but a purely NOTES technique has yet to be implemented in colorectal surgery. Hybrid techniques combining NOTES and laparoscopic techniques have yielded promising results in colorectal procedures such as colon resections. In order to further investigate this method, an experimental model using sheep was employed. Sheep were used to perform excision of the left colon using a transvaginal approach, which was chosen due to the similarity of external genital organs to female human genitals. Additionally, sheep share with humans a similar position of the left colon within the abdominal cavity. The totally transvaginal approach appears to be feasible in an animal model; however, application to the human population should be used with caution due to the technically challenging nature of the procedure and lack of long-term outcomes in the human patient population (Alba 2012). In addition to sheep models, porcine and rat models have also been used in colorectal surgery in order to further investigate sealing techniques of colorectal anastomoses in both *ex vivo* and *in vivo* models (Holmer 2011). Porcine models were used to evaluate the feasibility, safety, and efficacy of using a LigaSure device for dividing and sealing rectal stump during colorectal anastomosis creation versus a conventional stapler. The LigaSure device was found to be feasible in this experimental model but is less reliable than a stapler leading to a significantly greater fail rate (Sánchez-De Pedro 2014).

UROLOGY

Laparoscopy has gained increased importance in urology over the last twenty years, which has led to the development of laparoscopic reconstructive procedures such as

pyeloplasty, pelvic floor reconstruction, and radical prostatectomy. Training models include dry-lab, *ex vivo* animal models, and live animal models to be used for laparoscopic, robotic and endourologic training (Soria 2010; Aydin 2016). On porcine models, trainees are able to perform laparoscopic nephrectomy, ureteropelvic anastomosis, and suturing an incision on the bladder. Video trainers remain important in urologic laparoscopy training, but porcine laparoscopy has gained increased importance. Laparoscopic training on porcine models confers the benefits of training on animal models in general including haptic feedback, handling vitalized tissues that respond and bleed, and an overall similarity to real operative procedures; however, pig genitourinary anatomy is not identical to that of the human, which presents some limitations to this model. The pig has no retroperitoneal fat. The kidneys are adherent to the posterior abdominal wall and covered by a thin layer of peritoneum, which makes retroperitoneal dissection training difficult. Additionally, the ureter is thick and fatty with a narrow lumen. These anatomical limitations of the porcine model make human cadavers a popular alternative in urologic laparoscopic training (Katz 2003).

BARIATRIC SURGERY

Obesity continues to be a growing problem in the United States with an estimated 15.8 million adults qualifying for bariatric surgery (Ponce). Bariatric surgery techniques target weight loss through restriction, malabsorption, or a mix of both. The two most popular weight loss surgeries currently being performed are vertical sleeve gastrectomy (restrictive) and Roux-en-Y gastric bypass (mixed). Within laparoscopic and bariatric surgery, there has been a tendency for large laboratory animals such as pigs to be used. Bariatric experimental surgery on animals is useful for developing and perfecting techniques. Animal experimentation in bariatric surgery can also be used to study the relationship between metabolism and surgery in order to find improvements in treatment in the co-morbidities associated with morbid obesity. Lastly, research in this area can also focus on manipulating intake via central and vagal control (Del Castillo Dejardin 2004). Although it is now an abandoned malabsorptive technique, the jejunoileal bypass was previously the most studied bariatric surgical technique. Genetically-determined Zucker-type obese rats were used for the first time in bariatric research. From this research, subsequent studies of hormonal mechanisms responsible for weight loss and resolution of co-morbidities such as type 2 diabetes took place (Polyzogopoulou 2003). Current studies are aimed at further investigating the relationship between metabolism and surgery, specifically with gastric bypass in Zucker-type obese rats. This animal research looks at peptide hormones such as ghrelin, which regulates food intake and therefore plays a role in weight loss. In addition to Zucker-type obese rats, dogs and pigs have been used with the restrictive and mixed techniques with the goal of improving techniques for laparoscopy. Gastric persistalsis in reduction of intake is also being studied in rats, dogs, pigs, and rabbits in order to discover new options for patients in bariatric surgery. In order to draw meaningful conclusions, it is important to use obese animals in this area of research (Del Castillo Dejardin 2004).

GENERAL SURGERY

Inguinal hernia repair is one of the most frequently performed surgical procedures with over 800,000 hernia repairs performed annually in the USA. Despite the common nature of this procedure, key problems still exist following repair including complications secondary to invasive fixation of mesh, poor quality of tissue ingrowth induced by the mesh, and early mesh migration to and penetration into neighboring organs after implantation (Scheidbach 2004; Panaro 2015). Porcine animal models have been used for laparoscopic training purposes for hernia repairs for quite some time, but this animal model is further being utilized in order to compare surgical approaches and type of mesh used in hernia repairs. Polypropylene mesh is a common mesh used in millions of hernia repair operations, but variations in the type of polypropylene mesh used in repair result in a difference in their biocompatibility and handling characteristics during surgery. Porcine models may be used to further characterize these differences between mesh including shrinkage, chronic inflammatory reaction, and mesh incorporation into the surrounding tissue (Scheidbach 2004). Studies have also been done using the porcine model in order to further investigate various approaches to hernia repair including NOTES technique, totally extraperitoneal (TEP) and transabdominal preperitoneal (TAPP) (Dhumane 2013). Although this area of research may not purely focus on laparoscopic training, the results of such studies have a direct impact on the future standard of care in inguinal hernia repairs in patients.

PEDIATRIC SURGERY

Laparoscopic training outside of the operating room is of particular importance in pediatric surgery due to the increasingly complicated surgeries that are now being performed laparoscopically; however, the number of pediatric patients requiring these complicated procedures is usually small, which makes training outside of the operating room of the utmost importance in order to reduce complications and operating error. The porcine model is the most widely used animal model in laparoscopic training in fields such as adult minimally invasive surgery, colorectal, urologic and gynecological surgery. Despite this fact, very few studies have described the role of animal models for laparoscopic training in the pediatric population. Although the pig can be used in pediatric surgery training, the rabbit model could be helpful for pediatric surgery training due to its smaller size, which is comparable to the operative field encountered when operating on neonates and small children (Kirlum 2005). The piglet also poorly simulates the pediatric population due to its larger size weighing between 20 and 40 kg. In comparison, a rabbit that weighs 3–4 kg will have an abdominal cavity that measures approximately 15 cm long, 10 cm wide, and 8 cm high, which mimics the dimensions of the abdominal cavity in a newborn baby. Rabbits have been found to be good surgical models for repair of inguinal hernia and hiatal hernia due to their patent inguinal ring with retractile or intraabdominal testes and naturally gaping diaphragmatic hiatus, respectively. In contrast, it is difficult to mobilize the esophagus or perform cholecystectomy in the pig model due to its huge, multi-lobulated liver (Esposito 2016). Laparoscopic nephrectomy can also be challenging to perform in the porcine model due to the difficult access to the kidneys caused by large, distended bowel loops. Nephrectomy is more

straight-forward in the rabbit model due to the anterior location of the kidneys and scant intraabdominal and perineal fat (Molinas 2004). Other laparoscopic procedures can be performed additionally including intestinal anastomosis, splenectomy, and congenital diaphragmatic hernia repair. In an analysis of trainees' performances on rabbit versus porcine models, it was found that surgeons had higher performance scores and statistically shorter operative times for advanced procedures in the rabbit model. Overall, the rabbit model appears to provide a viable approach to technical training in basic and advanced laparoscopic procedures (Esposito 2016).

ALTERNATIVES TO ANIMAL SURGERY IN LAPAROSCOPIC SURGERY

Due to high costs, regulatory constraints, opposed public opinion, and complex logistics (maintenance, anesthesia) associated with animal experiments, other alternatives for training have been proposed. Simulation-based training allows trainees to further hone their laparoscopic skills in a safe, non-threatening environment prior to entering the operating room. The repetition of tasks and simulated procedures has been shown to reduce the risk of adverse surgical events and further decrease operating time (Hyltander 2002). Although training that occurs in the OR, on cadaver, and animal models may be a better method than simulation training, it appears that skills acquired in a simulation setting are transferable to the OR such as laparoscopic suturing and knot tying skills (Sutherland 2006; Al-Kadi 2013; Zendejas 2013). Simulation-based training can lead to demonstrable benefits of surgical skills in the operating room, and it is an effective way to teach laparoscopic surgery skills, increase translation of laparoscopic skills to the OR, and increase patient safety (Vanderbilt 2015). Numerous laparoscopic training tools exist, each of which have their own benefits and drawbacks.

A box trainer is a simple box that uses a camera, screen, light source and instruments. It incorporates conventional laparoscopic equipment in order to perform basic skills. It can be used for training on animal parts in addition to synthetic inanimate models. Complex task trainers are hybrid models that provide visual, audio and touch cues and use integrated hardware in order to replicate a clinical setting. They may also be composed of a partial component of a simulator or body part such as an arm or a leg. Video trainers are more sophisticated box trainers that have embedded motion sensors and recorders which measure distance and direction moved in order to calculate economy of movement. Table 1 lists the different types of training tools and their individual capabilities (Vanderbilt 2015; Alaker 2016).

In addition to physical box trainers and video trainers, virtual reality plays an increasingly large role in laparoscopic training; multiple modalities that utilize virtual reality for laparoscopic simulation training exist. Virtual reality uses screen-based computer software and hardware similar to that used in laparo-endoscopic surgery. Virtual reality (VR) can further be broken down into low-fidelity and high-fidelity groups. Low fidelity VR simulators use computer-training programs that provide an abstract environment to teach basic laparo-endoscopic skills whereas high-fidelity uses motorized instruments in order to provide haptic feedback and more closely resembles live tissue. Minimally Invasive Surgical Trainer – Virtual Reality (MIST VR), a part-task virtual reality laparoscopic simulator, not only

simulates surgical tasks and operations but is also able to provide an objective assessment of psychomotor skills by the operator. It will then generate an overall score, taking into consideration errors committed and time taken to complete six different tasks. When assessing surgical novices and practicing surgeons, experienced surgeons scored consistently and significantly better than their counterparts in all tasks, suggesting that the simulator is measuring surgically relevant parameters. Therefore, MIST-VR appears to be a validated tool in objectively assessing laparoscopic skills (Chaudhry 1999). In a systematic review and meta-analysis comparing virtual reality to other simulation models, it was found that virtual reality simulation was significantly more effective than video trainers and at least as good as box trainers in laparoscopic simulation training (Nagendran 2013; Alaker 2016). Moreover, virtual reality training appears to be a superior training method in comparison to standard laparoscopic training in the operating room (Gurusamy 2009; Al-Kadi 2012; Larsen 2012; Willaert 2013).

Table 1. Laparoscopic training tools, definitions, and procedures commonly used in surgery

Type of simulation	Definition	Camera Navigation	Clipping and cutting	Suturing and knot tying	Lifting and grasping	Dissection
Box Trainer	A box that incorporates conventional laparoscopic equipment to perform basic skills, is versatile, and enables training on animal parts and synthetic models	+	+	+	+	+
Task Trainer	A partial component of a simulator or simulation modality such as an arm, leg or torso		+	+		+
MIST-VR	Virtual reality simulator with six different tasks to simulate maneuvers performed during laparoscopic cholecystectomy in a computerized environment	+	+		+	+
LapMentor/ LapMentor II	Virtual reality simulator consisting of camera and two calibrated working instruments. Motion of the instruments is translated to a two-dimensional computer screen for student practices	+	+	+	+	+
LapSim	A computer-based simulator creating a virtual laparoscopic setting through a computer operating system, a video monitor, a laparoscopic interface containing two pistol-grip instruments, and a diathermy pedal without haptic feedback	+	+	+	+	+

Type of simulation	Definition	Camera Navigation	Clipping and cutting	Suturing and knot tying	Lifting and grasping	Dissection
EndoTower	EndoTower software consists of an angled telescope simulator composed of rotating camera and telescopic components.	+	+			
MISTELS/FLS trainer	McGill Inanimate System for Training and Evaluation of Laparoscopic Skills (MISTELS)- this inexpensive, portable, and flexible system allows students to practice in a virtual Endotrainer box		+	+	+	
SIMENDO VR	Computer software used to train eye-hand coordination skills by camera navigation and basic drills.	+		+	+	
URO Mentor	A hybrid simulator, consisting of a personal computer based system linked to a mannequin with real endoscopes. Cystoscopic and ureteroscopic procedures are performed using either flexible or semi rigid endoscopes	+	+		+	+
Da Vinci Skills Simulator	A portable simulator containing a variety of exercises and scenarios specifically designed to give users the opportunity to improve their proficiency with surgical controls.	+	+	+	+	+

Vanderbilt, A.A., et al., *Randomized Controlled Trials: A Systematic Review of Laparoscopic Surgery and Simulation-Based Training*. Global Journal of Health Science, 2015. 7(2): p. 310–327. This is an open-access article distributed under the terms and conditions of the Creative Commons Attribution license (<http://creativecommons.org/licenses/by/3.0/>). Table was not altered

Virtual or box trainer simulators have been shown to be effective at the beginning of training; however, fresh-frozen cadavers are another method of providing laparoscopic training that more closely resembles operating on patients. Cadavers provide full haptic and tactile feedback, which is vital in laparoscopic simulation and is unfortunately difficult to incorporate into virtual systems (Buckley 2014). They can also be stored at a low temperature for an indefinite amount of time (Sharma 2012). In comparison of cost, an initial fee is incurred to purchase with a small added cost for maintenance for simulators whereas cadaver bodies are typically donated free of charge; however, high cost is associated with maintenance of a cadaver laboratory and cremation of used bodies. Other drawbacks to use of cadavers for training include limited availability, avital tissues, and inability to injure vasculature or other structures (Sharma 2012; Ryska 2016).

Robotic surgery continues to grow in popularity worldwide. Although it is a derivative of minimally invasive surgery, the skills required to perform robotic surgery are unique from those required in either open or laparoscopic surgery. There are currently four commercially available simulators: the da Vinci Skills simulator (dVSS), the Mimic dV-Trainer (dV-Trainer), the Robotic Surgical Simulator, and Sim-Surgery Educational Platform (SEP). All four trainers are able to assess robotic skill. Three of the four simulators (dVSS, dV-Trainer, RoSS) demonstrate the ability to improve basic robotic skills, with proficiency-based training being the most effective training style. The skills obtained on a VR training curriculum appear to be similar to those obtained through dry laboratory simulation (Bric 2016).

An alternative to virtual reality simulators and fresh frozen cadavers is the Open-source Heidelberg laparoscopy phantom (OpenHELP), which combines realistic anatomy and tissue properties with reusable simulation specimens. OpenHELP is based on a digital three-dimensional model obtained from a CT scan of a male body and uses a flexible torso, via an elastic abdominal wall, or rigid, with a plastic shell, filled with artificial organs made from silicon casts. Pneumoperitoneum could successfully be attained by both methods (Kenngott 2015). As NOTES become more prevalent, training models specific for this technique are needed. A new training model for the NOTES procedures was developed known as the endoscopic-laparoscopic interdisciplinary training entity (ELITE). This model is composed of a synthetic package with all the intrabdominal organs, including the greater omentum. The synthetic appendix is made from gelatin material, which allows for dissection with high-frequency tools. The ELITE training model appears to be well suited for the training of NOTES procedures (Gillen 2012).

In addition to *in vivo* training, pieces of animal tissues may also be removed from the animal specimen and be used to recreate the anatomic conditions of a specific procedure. When used for this purpose, the animal tissue is traditionally placed in a pelvic trainer or dry box in order to more closely simulate a specific laparoscopic surgery for the trainee. Animal tissue may also be placed in human body simulators in order to more closely imitate both human anatomy and realistic operating conditions by including real tissue that will allow tactile feedback and will respond when being manipulated. The advantages of using pieces of animal tissue include high availability, low cost, lack of need for anesthesia, and no animal maintenance (van Velthoven 2006).

LAPAROSCOPIC SURGERY IN SMALL ANIMAL MODELS

A wide variety of small animal models exist in order to provide a sophisticated training model for the advanced laparoscopic trainee. Each of these models not only have advantages and disadvantages, but they also possess characteristics which may make them better suited for certain surgical sub-specialties over other small animal models. Overall, the ideal training model should provide the skills required, be inexpensive, universally available, and anatomically and physiologically identical to the anesthetized patient. Mice, rats, rabbits, and guinea pigs are universally accepted and are bred for both surgical and medical research due to cheaper costs, easy handling and care, and a more favorable public opinion. Although primates such as monkeys and apes most closely represent humans physiologically and anatomically, the use of primates is limited only to special circumstances in which any other

animal model would be deemed unreliable. Animal models are typically utilized for reproduction of the following systems for training purposes due to the relative ease of reproducing surgical conditions: musculoskeletal, genitourinary, integumentary, vascular, cardiothoracic, and digestive system (Hassan 2005).

Mice, despite being studied extensively and being ideal for immunologic or oncologic studies, are too small to be used in laparoscopic procedures. On the other hand, the larger animal model, the rat, has been previously used for laparoscopic training such as in transperitoneal laparoscopic research (Gutt 1998). The rat model is inexpensive and easily handled due to size. This model has previously been described as a model for retroperitoneal mini laparoscopic nephrectomy, but the rat can also be used universally throughout laparoscopic sub-specialties as a way for the trainee to acquire advanced laparoscopic skills and microsurgical suturing skills (Kaouk 2000). However, due to the limited workspace, the rat model requires the trainee to have already acquired the skills necessary to work with 3-mm instruments in a very small space.

In comparison to the rat model, the rabbit model is not only inexpensive but also provides a larger workspace, which makes it a more realistic model. This model has been used as an *in vivo* training model for laparoscopic skills such as knot-tying, suturing, and using cutting and coagulation modes for dissection (Molinas 2004). The rabbit model has been shown to be well-suited for the use as a new training tool that emphasizes the repetition of simple procedures due to its ability to easily monitor progress when comparing learning curves between experienced and inexperienced surgeons such as gynecologists and medical students, respectively. With additional practice, shorter operating times and fewer complications were noted. This small animal model is also being used in experimental settings to evaluate the oxidative stress production on a transplanted kidney during laparoscopy (Demirbas 2004). As previously discussed, the rabbit model provides a very realistic model for pediatric surgery training due to the small operative field similar to that seen in the pediatric population. Due to the potential risks of carbon dioxide pneumoperitoneum in the neonate and infant population, the concept of gasless laparoscopy was first developed in the rabbit model. In the gasless model, the animals were neither intubated nor mechanically ventilated. After incision was made and the peritoneum was entered, an abdominal wall elevator was inserted which provided excellent visualization of the abdominal cavity (Luks 1995).

At the Center for the Development of Advanced Medical Technology (CDAMTec) in Japan, both wild-type and genetically modified pigs are used as multi-purpose models for medical skill education, the development of therapeutic strategies, and innovations for new tools for endo- and laparoscopic procedures. Unlike dogs, few spontaneous disease models exist in pigs. Pigs also share similar immune systems with humans as seen in inbred pigs such as the Clawn minipig, which further allows genetically modified pigs to be used in experimental models for liver, intestine, kidney, pancreas, and lung transplantation (Kobayashi 2012). At the CDAMTec research center, three different types of pigs are used: domestic pigs, miniature pigs, and genetically modified miniature pigs as seen in Figures 10 and 1.11. Pigs may vary in size from 30 to 40 kg as young pigs to approximately 100 kg once at mature body weight. Domestic pigs are easily obtained and are inexpensive since they are well established as a food source. Miniature pigs are generally easier to handle; however, they are more expensive than domestic pigs due to their limited annual production for experimental use in Japan. A mature miniature pig weighs 40 to 50 kg, similar to the weight seen in immature domestic pigs. In order to use the pigs available more effectively, after they

have been euthanized, their tissues can undergo “second use” after being donated to other researchers for additional experiments, which ultimately results in fewer total number of experimental animals needed for research and decreases the other resources that are set aside for the proper care and disposal of animals after being euthanized (Tanaka 2006).

Table 2. Advantages and disadvantages of *ex-vivo* and *in-vivo* models

Models	Applications	Advantages	Disadvantages
<i>Ex-vivo</i> (non-perfused) models	• Compare the efficacy of different antenna configurations. • Trial of different energy settings	• Allow histological examination of whole lesion to study zones of tissue after thermal energy (i.e., ablation) applied • Inexpensive • Larger study sample size • Easy to manipulate during experiment • Does not require ethical approval/animal license	• Non-physiological • Homogenous parenchyma • Absence of respiratory excursion and motion of subject being studied • Lack of cooling effect secondary to tissue perfusion • Inability to study heat sink effect
<i>In-vivo</i> models	• Study of lesion evolution over time • Histological examination of lesion • Study of heat sink effect • Study of systemic responses to thermal energy applied • Study of effect of large volume thermal energy applied to tissues (in larger animals)	Small animals • Easier to handle • Cheaper • Ability to have larger sample size Large animals • Closer resemblance to human anatomy and physiology (for example, the liver)	Small animals • Small organ volume (i.e., liver) • Not suitable for the study of large volume thermal energy application (i.e., ablation) Large animals • Size and temperament poses challenges during anesthesia • Difficult vascular access in porcine models • Limited by strict ethic regulation • Small study sample size
Isolated perfused <i>ex-vivo</i> models	• Study of lesion evolution over time • Study of heat sink effect • Study of early inflammatory response	• Cheaper than <i>in-vivo</i> experiments • Does not require ethical approval • Greater control of perfusion characteristics (i.e., in liver, portal vein and hepatic arterial flows and pressures)	• Expensive • Expertise in animal handling and anesthesia is required • Duration of study is limited to the lifespan of the model • Absence of interacting organ systems • Inability to assess the impact of thermal energy on end organs • Perfusion circuit itself may activate some degree of systemic response

LIMITATIONS OF ANIMAL MODELS

Animal models in laparoscopic training act as a great tool to help trainees improve their laparoscopic skills in a setting that closely resembles operating on patients. However, animal experimentation has several drawbacks including cost, availability, time required to provide adequate care to the animals both before and after operative intervention, and the ethical implications of using animals for medical experimentation. From a legal perspective, these experiments are likely to continue on animals until viable alternatives exist for testing prior to introduction of certain surgical procedures to the general public or until legislation allows the introduction of surgical treatment to the general public without first being tested on animals.

The Greeks described animal experimentation almost 2500 years ago when both Aristotle and Erasistratus performed studies on live animals (Singer 1922; Wilson 1959). Once general anesthesia emerged in the 1840s, this allowed unconscious animals to be studied, which led to a turning point in the medical and scientific communities' ability to use animal models in

surgical experimentation. Animals can be used either as *ex vivo* or *in vivo* models. The major limitations of *ex vivo* models include absence of blood flow and vitalized tissues, which will respond to movement and maneuvers performed by the surgeon, and they also have limited lifespans during which valid data can be obtained. The absence of other interacting organs in *ex-vivo* models may also affect the extent of systemic responses during experimentation. The use of living animals with *in-vivo* studies requires specific laboratory facilities and research teams with expertise in anesthetizing and handling different species. The size of the animal also poses a barrier, for example when a larger animal such as a pig or cow needs to be anesthetized, moved, or examined post-operative (Hildebrand 2007; Ong 2013). The advantages and disadvantages of *ex vivo* and *in vivo* models for experimentation are compared in Table 2.

FUTURE OF LAPAROSCOPIC SURGERY

Laparoscopic surgery has evolved immensely from its initial use as a diagnostic procedure to the first laparoscopic cholecystectomy being performed in 1985 to its widespread use across all surgical subspecialties. Laparoscopy has further developed over the last thirty years in part due to the development of new instruments, which allows more complex operations to be performed. Laparoscopic camera equipment is now available in high-definition, with automatic focus and zoom, and three-dimensional images. Several different types of energy devices are now available including monopolar electrocautery scissors, ultrasonic coagulating shears, and electrothermal bipolar vessel sealers, which can be used for dissection and division of tissue, bowel, and vascular structures (Blackmore 2014). The development of new surgical instruments and imaging devices expands not only the type of surgery but also the surgical fields that are now able to use laparoscopy. In addition to these new contributions to the field, laparoscopy continues to evolve through different methods in which laparoscopic surgery can be performed including robotic surgery, single incision laparoscopic surgery (SILS), natural orifice transluminal endoscopic surgery (NOTES), and three-dimensional laparoscopy.

Robotic surgery was first seen in the field of urology and cardiac surgery with over 50,000 robotic prostatectomies being performed in 2007 in the USA alone. It was not used in colorectal surgery until 2002 (Blackmore 2014). Robotic surgery confers several advantages including high-definition three-dimensional visualization, increased freedom of movement, and minimization of tremor. These advantages provide for a more controlled, delicate dissection compared to laparoscopy. Several urologic procedures are now routinely being performed robotically including radical prostatectomy, transperitoneal and retroperitoneal partial nephrectomy, radical nephrectomy with caval thrombectomy, and pyeloplasty (Rogers 2008; Abaza 2011; Patel 2013; Stepanian 2016). Studies have indicated that robotic-assisted partial nephrectomy is associated with excellent outcomes in terms of perioperative complications and functional results when performed by experienced surgeons. Robotic surgery could potentially also be applied to removal of complex tumors (Novara). Robotic technology has also been extended to liver surgery and represents an accepted alternative to open and laparoscopic techniques in certain cases. Robotic liver surgery allows precise dissection and microsuturing in narrow operative fields, and with this technology, there is

greater potential for more major resections and difficult segmentectomies to be performed through minimally invasive methods. Current data suggests that robotic liver resections have at the very least similar perioperative and postoperative outcomes while conferring the general benefits of minimally invasive surgery. Advantages of minimally invasive robotic surgery appear to be able to be applied additionally to right hepatectomy for living liver donors including faster post-operative recovery. Similar early allograft dysfunction, complications, and one-year recipient liver function were found between the open and robotic groups (Chen 2016). The technology used in robotic surgery also helps integrate and facilitate newer technologies such as near-infrared fluorescence (Giulianotti 2016). However, there are limitations to robotic surgery, which include higher associated costs and the need for specialized training for the primary surgeon, secondary surgeon, and OR nurses.

The next step to decrease the invasiveness and improve cosmesis of laparoscopic surgery is to decrease the size and number of incisions made as seen in single incision laparoscopic surgery (SILS). Through this technique, all instruments are introduced into the body cavity through a single access port. As laparoscopy has resulted in decreased trauma to the abdominal wall, improved pain control, and quicker recovery post-operatively, single-site incision surgery has further capitalized on these advantages of minimally invasive surgery by decreasing the number of incisions made. However, SILS requires a skill set and has ergonomic demands, which cannot directly be adapted from laparoscopic surgery. Therefore, in order to avoid higher complication rates as seen in both early laparoscopic cases and now initial SILS cases, evidence- and competency-based SILS curriculum should be instituted.

The first reported SILS cholecystectomy was performed in 1995 with new applications to other fields such as appendectomies and complex bariatric procedures. As was seen in the early days of laparoscopic surgery, increased complication rates at the advent of SILS makes it clear that appropriate training should occur before utilizing this technique on patients. The Laparoendoscopic Single-site Surgery Consortium for Assessment and Research (LESSCAR) set out a 2009 whitepaper, which addresses some of the issues regarding appropriate training for new techniques. LESSCAR recommends a stepwise format for training with a progression from inanimate models to animal procedures to supervised human SILS cases. These are the same principles that can be applied to laparoscopic or robotic training. As seen in case studies that examine SILS outcomes, there exists a significant learning curve even for laparoscopic surgeons who adopt SILS as seen through greater operative time and increased conversion from single to multi-port laparoscopy. Skills required for SILS do not appear to be automatically conferred from laparoscopic surgery, which further makes it important that adequate, safe training is available in order to make surgeons proficient (Pucher 2013). Needlescopic cholecystectomy is an additional method, which further reduces traumatic stress during and after surgery and hastens full recovery. A meta-analysis comparing needlescopic versus laparoscopic cholecystectomy indicated that needlescopic is not only safe and effective procedure for management of gallstone disease, but it is superior to laparoscopy for less post-operative pain and better cosmetic results despite being associated with longer operative time and higher conversion rate.

Natural orifice transluminal endoscopic surgery (NOTES) has gained traction in the surgical community as a technique to further advance minimally invasive techniques towards being truly non-invasive (Figure 12). This method requires a flexible endoscope to be inserted via a natural orifice such as the mouth, anus, vagina or umbilicus in order to gain access to the abdominal cavity thereby without leaving a scar. NOTES has gained popularity as a method

to perform cholecystectomy or appendectomy. NOTES is truly a non-invasive surgery since it eliminates external postoperative wounds and other advantages including reduction in trauma to the abdominal wall, decreased recovery time, decreased clinical costs, and improved overall cosmetic results (Spivak 1997; MacFadyen 2005; Richards 2005; Ponsky 2006). Initial clinical outcomes following transvaginal hybrid NOTES cholecystectomy indicate that this method appears to be safe when performed by appropriately trained surgeons and may result in a faster return to normal activities and decreased postoperative pain (Sodergren 2015).

As with any new operative technique, appropriate training and investigation into post-operative outcomes should be performed prior to routine use of the NOTES technique. Differences between laparoscopic and NOTES procedures are that the NOTES technique requires the surgeon to operate an endoscope and other instruments through a single access point, rather than three or four other ports as frequently used in laparoscopy. Many NOTES procedures are currently being performed via hybrid fashion in which both an endoscope and trans-abdominal instruments are used; however, there is still significant loss of traction and the in-line instrument approach using the instrument ports in the endoscope hand-piece remain unfamiliar to most surgeons. Additionally, there is no gastrointestinal lumen to support the endoscope; thus, the distal end of the endoscope is manipulated in the open abdominal cavity using the incision site, internal organs and gravitational force to navigate and position the endoscope and instruments. As a result, the middle section of the endoscope is prone to rolling and twisting in the abdomen. Similar to SILS, the skill set required to operate an endoscope and associated surgical instruments is unique and cannot be directly transferred from laparoscopic and endoscopic skills (Korzeniowski 2016). Virtual reality simulators have found to be effective training tools for other minimally invasive techniques; however, a virtual reality trainer specific to NOTES procedures is required in order to proceed with further training. As a result, the natural orifice virtual surgery (NOViSE) simulator was developed due to the lack of established curriculum for NOTES training. NOViSE is a first prototype whose main focus is teaching the endoscopic manipulation skills required for NOTES and includes integration of a force-feedback-enabled virtual reality simulator for NOTES training with a virtual flexible endoscope. NOViSE is currently only able to simulate trans-gastric hybrid cholecystectomy procedure using a flexible endoscope as seen in Figure 12. Promising initial results following its implementation as a training device indicate that may be able to contribute to surgical training and to improving technical skills for NOTES procedures without putting patients at risk (Korzeniowski 2016).

One of the challenges of laparoscopic surgery is that surgeons face the loss of depth perception and spatial orientation due to the fact that they are working in a three-dimensional (3D) space but being guided by two-dimensional (2D) images. This disadvantage leads to a high visual and cognitive load. Therefore, 3D imaging was developed as an alternative to conventional 2D imaging. 3D imaging was introduced as early as the 1990s; however, its use is still not standard at hospitals, which may be secondary to the degraded view of the operative field resulting from poor image resolution, the necessity to wear uncomfortable eyewear (which alone can lead to eye strain, headaches, dizziness, and physical discomfort), and high cost. However, as technology has further evolved and high-definition monitors are now available, these disadvantages may be minimized when using the newest technology (Sorensen 2016). Overall, 3D laparoscopy appears to confer a reduction in performance time, is more affordable than robotic systems, and a reduction in errors is observed when compared

to 2D technology. Most importantly, however, 3D laparoscopy allows improved depth perception, which is significant due to the fact that most common laparoscopic injuries occur due to visual misperceptions (Way 2003).

CONCLUSION

The prevalence of laparoscopy throughout surgery has increased exponentially over the past thirty years. As laparoscopy as a field has continued to grow, its applications are being applied to both new surgical procedures that previously were only being performed open, and an increasing number of surgical subspecialties are using laparoscopy. As a result, laparoscopic experimental surgery models have played a crucial role in surgical training, which ultimately impacts the diversity of surgical procedures that may be safely performed in patients. Animal models are the ideal training model to be used in laparoscopic surgery training because they confer the benefits of ideal haptic feedback, handling vitalized tissues that respond and bleed, and an overall similarity to real operative procedures. Animal experimental models have been crucial to the development of new techniques and procedures and for the training of surgeons in laparoscopic surgery. Due to its success, laparoscopy and other minimally invasive procedures have been applied to more complex surgeries in fields such as hepatobiliary, transplant, colorectal, and pediatric surgery. Laparoscopy and other minimally invasive techniques such as robotic surgery and NOTES require their own set of surgical skills, which makes it imperative that proper training is available prior to both novice surgeons using basic techniques and experienced surgeons using advanced or new techniques

on patients. Laparoscopic trainers, virtual reality, cadavers, and *in vivo* animal models are all options for laparoscopic training with in-vivo animal models providing the most real-to-life models for practice due to their anatomical and physiologic similarities to humans. As minimally invasive surgery continues to evolve from laparoscopy to robotic, single-incision laparoscopic surgery, and NOTES procedures, the need for additional animal training will be a necessity in order to ensure optimal outcomes for patients.

ABSTRACT

Sepsis is a clinical syndrome manifesting as a complex systemic response to infection. In spite of significant developments in diagnostic, monitoring and intensive care, sepsis remains a major cause of morbidity and mortality as well as a significant economic burden. Despite inherent limitations, experimental models remain an essential tool for understanding the intricate mechanisms and pathways activated during sepsis and for developing new therapeutic approaches. However, most strategies proved as effective experimentally, have been disappointing in the clinical trials conducted so far. These unsatisfactory attempts in translating the treatment options to bedside may be attributed to the involvement of multiple mediators and pathways in sepsis with only few components being recognized and targeted but also to general or specific shortcomings of each animal model. Herein, we provide a brief overview of the pathophysiology of sepsis and concise descriptions of relevant experimental models including considerations for further refinements (i.e., animal age, gender and co-morbidities) that are further required to ensure an effective translation of the findings into the clinical setting.

Keywords: sepsis, animal models, clinical versus experimental sepsis

ABBREVIATIONS

ARDS	acute respiratory distress syndrome
AST	<i>aspartate aminotransferase</i>
ATP	adenosine triphosphate
CASP	colon ascendens stent peritonitis model
CLP	cecal ligation and puncture model
DIC	disseminated intravascular coagulation
EVLW	extra-vascular lung water
GCS	Glasgow Coma Scale
HR	heart rate
ICU	intensive care unit
IL	interleukin
LPS	lipopolysaccharide
MAP	mean arterial pressure
MODS	multiorgan dysfunction syndrome
MOF	multiple organ failure
NF κ B	nuclear factor kappa B
NO	nitric oxide
NOD	nucleotide-binding oligomerization domain-like (<i>receptor</i>)
PEEP	<i>positive</i> end-expiratory pressure
<i>PiCCO</i>	Pulse index Continuous Cardiac Output monitoring device
SIRS	systemic inflammatory response syndrome
SOFA	sequential organ failure assessment (score)
TLR	toll-like receptor
TNF- α	tumor necrosis factor alpha

INTRODUCTION

The last decades witnessed a tremendous increase in the volume of research and number of publications on sepsis, both in clinical and experimental setting (Figure 1). Despite the advancement of the diagnostic and therapeutic possibilities and the accumulating evidence-based treatment options, sepsis remains a main cause of death in the intensive care units (ICU) of developed countries. According to a recent report, there have been 31.5 million cases of sepsis annually, among them 19.4 million severe cases, with potentially 5.3 million deaths occurring annually (Daniels 2011; Fleischmann 2016).

A better understanding of the pathophysiology of the sepsis and the development of novel therapeutical methods require a great deal of animal experimentation. Publications on animal sepsis have increased in logarithmic fashion in the past decades (Figure 1). Although rodents remain the most common species used, other species are also subjected to sepsis studies (Figure 2). Depending on the goals of each particular study and the peculiarities of various models and species, each existing model has different advantages but also result in several limitations and difficulties when extrapolating results into the clinical scenarios or trials (Fink 2001; Esmon 2004; Bara 2014; Kingsley 2016).

Planning and conducting a sepsis study on animals requires careful consideration of numerous essential aspects that may influence the results, conclusions and the as well as the reproducibility of the study. In this chapter we aimed to briefly overview the clinical problem, pathophysiology, the animal models, their advantages and limitations.

Figure 1. Number of publications per year on the human and animal sepsis (PubMed search, 12 November 2016).

Figure 2. Number of publications per year on animal sepsis by species (PubMed search, 12 November 2016).

In the last decades, increasing number of papers have been published on sepsis, both in clinical and experimental settings (Figure 1).

To better understand the pathophysiology of sepsis and to develop therapeutic methods, experiments conducted on animals are still necessary. Publications on animal sepsis have increased significantly in the past decades (Figure 1). Although the most common species are

rodents, other animals such as dog, pig, sheep and non-human primates are also used in sepsis studies in a significant number (Figure 2). However, the models are different; besides their advantages, animal models have several limitations and difficulties when extrapolating results. These issues have been discussed in the literature intensively in the last decades (Wichterman 1980; Fink 2001; Schulz 2002; Esmon 2004; Remick 2005; Rittirsch 2007; Chiavolini 2008; Poli-de-Figueiredo 2008; Dyson 2009; van der Poll 2012; Ward 2012; Ziaja 2012; Bara 2014; Chen 2014; Efron 2014; Fink 2014; Shrum 2014; Lilley 2015; Kingsley 2016; Lewis 2016). To plan and conduct a sepsis model using animals, there are numerous essential aspects to consider.

CLINICAL DEFINITIONS OF SEPSIS

It is noteworthy that the past three decades have seen various definitions for sepsis and severe sepsis. Initially, sepsis was defined as a clinical response arising from infection, independently from the cause of infection (bacterial, viral or fungal) (American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference 1992). This initial definition also introduced the concept of systemic inflammatory response syndrome (SIRS).

It has been postulated that sepsis and SIRS have similar clinical appearance, although, major differences exist among the underlying causes (i.e., infections and non-infections causes such as, burns, trauma). At this stage, sepsis was defined based on simple clinical criteria such as: body temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$; pulse rate $>90/\text{minutes}$; breathing frequency $>20/\text{minutes}$ and/or $p\text{CO}_2 <30 \text{ mmHg}$; leukocyte count $>12 \text{ G/l}$ or lower than 4 G/l along with more than 10% immature forms. For making the diagnosis of sepsis, two of the above listed parameters were necessary to be present. At that time, severe sepsis was defined as basic symptoms of sepsis plus organ dysfunctions, hypotension and hypoperfusion related to infection. Consequently, a very large number of patients were diagnosed as having sepsis based on these criteria.

The next attempt to revise this definition retained these clinically determined criteria, further stating that an expanded list of signs and symptoms of sepsis may better reflect the clinical response to infection, but also included several biochemical markers for use in septic patients (Table 1) (Levy 2003). In its very recent definition, sepsis is described as a “*life threatening organ dysfunction caused by a dysregulated host response to infection*” (Singer 2016).

The key points to be taken into account according to this newly developed definition are heterogeneity of the patients that is influenced by underlying co-morbidities, concurrent injuries (such as surgery), medications and source of infections. This statement differentiates sepsis from infection. Sepsis is an aberrant or dysregulated host response and the presence of organ dysfunction. Accordingly, the main definitions of the septic process are as follows:

- *Sepsis* is defined as life-threatening organ dysfunction caused by a dys-regulated host response to infection.
- *Organ dysfunction* can be identified as an acute change in total SOFA score >2 points consequent to the infection.

- *Septic shock* is a subset of sepsis in which underlying circulatory and cellular/metabolic abnormalities are profound enough to substantially increase mortality. Patients with septic shock can be identified with persisting hypotension requiring vasopressors to maintain MAP >65 mmHg and having a serum lactate level, >2 mmol/L (18 mg/dL) despite adequate volume resuscitation.

The main categories of Sequential Organ Failure Assessment Score (SOFA Score) are summarized in Table 2 (Vincent 1996).

Table 1. Diagnostic criteria for sepsis according to the 2001 definition (Levy 2003)

Infection
Documented or suspected <i>and</i> some of the following:
General parameters
Fever (core temperature >38.3°C)
Hypothermia (core temperature <36°C)
Heart rate >90 bpm or >2 SD above the normal value for age
Tachypnea: >30 bpm
Altered mental status
Significant edema or positive fluid balance (>20 ml/kg over 24 h)
Hyperglycemia (plasma glucose >110 mg/dl or 7.7 mM/l) in the absence of diabetes
Inflammatory parameters
Leukocytosis (white blood cell count >12,000/ μ l)
Leukopenia (white blood cell count <4,000/ μ l)
Normal white blood cell count with >10% immature forms
Plasma C reactive protein >2 SD above the normal value
Plasma procalcitonin >2 SD above the normal value
Hemodynamic parameters
Arterial hypotension (systolic blood pressure <90 mmHg, mean arterial pressure <70, or a systolic blood pressure decrease >40 mmHg in adults or <2 SD below normal for age)
Mixed venous oxygen saturation >70%
Cardiac index >3.5 l min ⁻¹ m
Organ dysfunction parameters
Arterial hypoxemia (PaO ₂ /FIO ₂ <300)
Acute oliguria (urine output <0.5 ml kg ⁻¹ h ⁻¹ or 45 mM/l for at least 2 h)
Creatinine increase $\geq$ 0.5 mg/dl
Coagulation abnormalities (international normalized ratio >1.5 or activated partial thromboplastin time >60 s)
Ileus (absent bowel sounds)
Thrombocytopenia (platelet count <100,000/ μ l)
Hyperbilirubinemia (plasma total bilirubin >4 mg/dl or 70 mmol/l)
Tissue perfusion parameters
Hyperlactatemia (>3 mmol/l)
Decreased capillary refill or mottling

Table 2. The Sequential Organ Failure Assessment or Sepsis-related Organ Failure Assessment score (SOFA) score (Vincent 1996)

	0	1	2	3	4
Respiration					
PaO ₂ /FiO ₂ (mmHg)	>400	<400	<300	<200 with respiratory support	<100 with respiratory support
Coagulation					
Platelets (x10 ³ /μL)	>150	<150	<100	<50	<20
Liver					
Bilirubin (μmol/L)	<1.2	1.2–1.9	2.0–5.9	6.0–11.9	>12
Cardiovascular					
	MAP >70 mmHg	MAP <70 mmHg	Dopamine < 5 or dobutamine any dose	Dopamine 5.1-15 or epinephrine <0.1 or norepinephrine < 0.1	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1
Central nervous system					
GCS	15	13–14	10–12	6–9	< 6
Renal					
Creatinine (μmol/L)	<110	110–170	171–299	300–440	> 440
Urine output (mL/D)				< 500	< 200

Figure 3. The involvement of macrophages in the septic process.

A BRIEF OVERVIEW ON THE PATHOPHYSIOLOGY OF SEPSIS

In recent decades it has become clear that different pathogens exert their action by interacting with specific targets (represented by toll-like receptors) at the surface of various cell types. In case of non-infectious origin, SIRS is evoked through the activation of the nucleotide-binding oligomerization domain-like (NOD) receptors. Macrophages are key actors in the process as activation of their NF- κ B by protein kinases results in the production of pro- and anti-inflammatory cytokines triggering the general inflammatory process (Figure 3). As it is demonstrated in the figure, the “cytokine storm” causes gradual changes at the level of capillary function and coagulation system. These complex changes determine the severity of SIRS and sepsis in their later course (Brides 2005; Remick 2007; Wynn 2010; Nduka 2011; Dellinger 2013; Semeraro 2015; Bhan 2016). In the view of this, in the following sections, we summarize the main pathophysiological alterations and their consequences in different organ systems.

Causes of Capillary Dysfunction in Sepsis

The capillary network is responsible for the transport of oxygen and the main nutritional products to the tissues. Its function is influenced by the distribution of the capillary network in certain tissue, by the actual condition of the capillaries (dilated or constricted), by the inter-capillary distance and by hemorheological factors (Further details in Chapter 34).

Sepsis is currently considered as a microcirculatory disorder (Astiz 1995; Ince 2005, 2016; Trzeciak 2007, 2008; Tyagi 2009; Ostergaard 2015). The microcirculatory failure usually is generalized; however, it is often tested on the sublingual surface and/or on skin (Young 1995; Trzeciak 2007, 2008; Wester 2011; Kiss 2015). Factors leading to microcirculatory problems in sepsis are complex. Several mechanisms act on the pre-capillary, capillary and post-capillary regions of the microcirculation, as summarized in Table 3.

The mechanisms leading to deterioration of micro-rheological factors are dominantly non-specific. Red blood cell deformability can be impaired by (1) local metabolic and acid-base changes (pH, lactate concentration, oxygenation level, micro-environmental osmolarity); (2) decrease in ATP and consequent failure of active pump mechanisms, a condition that leads to alteration in surface to volume ratio; as well as by (3) reactive oxygen species (Baskurt 2007; Piagnerelli 2003; Nemeth 2012). Red blood cells can be damaged mechanically as well due to the presence of thrombi and micro-thrombi (DIC), or even by the associated mechanical trauma to blood during therapeutic efforts such as the direct removal of toxins from the bloodstream by high-volume hemofiltration (Kameneva 2007; Borthwick 2013).

Enhanced red blood cell aggregation is a common observation in manifest sepsis. In most of the clinical and experimental studies, the developed sepsis and severe sepsis has been found with increased fibrinogen and plasma viscosity, impaired red blood cell deformability and markedly enhanced erythrocyte aggregation (Chien 1972; Baskurt 1997; Kirschenbaum 2000; Piagnerelli 2003; Pöschl 2003; Alt 2004; Sordia 2006; Moutzouri 2007; Reggiori 2009). The rise in fibrinogen concentration is one of the factors that lead to enhanced

erythrocyte aggregation. Furthermore, free radical effects, ultrastructural alterations of the cell surface glycocalyx as well as cellular morphology changes might also influence red blood cell aggregation in its magnitude and kinetics (Baskurt 2007, 2012; Nemeth 2012). However, it has been also shown in a porcine model of fulminant sepsis that during the early phase of the process, the red blood cell aggregation might be decreased (Nemeth 2015, 2016), probably due to the early fibrinogen consumption (Asakura 2014; Semeraro 2015), the direct effect of NO and the bacteria themselves (*Escherichia coli*) on erythrocytes.

Table 3. Events and factors leading to microcirculatory disturbances in sepsis (based on papers by Piagnerelli 2003; Spronk 2004; Lundy 2009)

Event, factor	Dominant site of the effect
vasodilatation and vasopressor hyporeactivity (vasoplegia)	arterioles
redistribution of organ blood flow, hemodynamic changes	
congestion, intravascular pooling	arterioles, venules
opening AV shunts	
endothelial cell activation, endothelial dysfunction	arterioles, capillaries, venules
hemorrhage	
decreased neutrophil deformability	
enhanced neutrophil aggregation	
impaired red blood cell deformability	
microthrombi, DIC	
increased plasma viscosity	
increased microvascular permeability	capillaries
edema formation	
neutrophil adhesion and aggregation	capillaries, venules

Deformability of neutrophils also decreases and their aggregation increases in severe sepsis and septic shock (Yodice 1997; Nishino 2005; Brown 2006). Adhered leukocytes affect local flow pattern and rigid cells may plug microcapillaries. Furthermore, altered blood rheology drives margination of the leukocytes: increased erythrocyte aggregation enhances axial flow, resulting in a widening cell deprived layer (Poiseuille-zone) in the vicinity of the endothelial surface, and so the flow pattern facilitates leukocyte tethering and margination (Nash 2008).

Capillary perfusion is usually described by the term ‘capillary driving pressure’ and by the actual condition of the pre- and post-capillary sphincters. Low volume state during sepsis may be attributed to 2 main factors: (1) Due to the peripheral vasodilation, a large amount of fluid is stored in the dilated vessels; and (2) due to capillary leak, a large amount of fluid may leave the intravascular compartment thus resulting in an interstitial fluid accumulation. Capillary leakage is also believed to be the consequence (at least in part) of the excessive NO production of the endothelium. From experimental observations, it is known that high levels of NO decreases the cyclic opening-closing function of the endothelial tight junctions and it is believed that this is a key factor in capillary leakage (Gomez-Jimenez 1995; Morel 2013). Additionally, activated leucocytes and complement enzymes may also damage capillary wall integrity.

Based on experimental observations, dominantly precapillary sphincters in gram-positive sepsis are dilated, while in case of gram-negative pathogens, this phenomenon occurs at the level of postcapillary sphincters. Thus, capillary perfusion itself is also influenced by the actual pathogen causing the septic process. Taking into account that capillary driving pressure is also influenced by systemic blood pressure, low systemic blood pressure that develops in severe sepsis, may result in a decreased capillary driving pressure. Due to local regulatory mechanisms, when driving pressure decreases, capillary sphincters get further dilated in order to enhance local blood flow. Unfortunately, as shown in Figure 3, coagulation system is also activated during the septic process leading to micro-thrombi formation and thus resulting in worsening of the local oxygen and nutritional transport.

Alterations in lymphatic flow also show a blend picture in sepsis. Endotoxaemia can be associated with an increase in thoracic duct lymph flow (Kutner 1967; Williemas 1973; Smith 1988). When the thoracic duct was ligated in a canine model of peritonitis sepsis, it had a negative effect on liver function and survival; bacterial count in peritoneal fluid, endotoxin level in portal vein, nitrite and AST level were significantly elevated (Guler 1999). In a porcine model, Lattuada and Hedenstierna (Lattuada 2006) found that during endotoxin sepsis (LPS infusion), the lymph flow from the abdomen increased. The flow was measured by ultrasonic probe placed around the thoracic duct. They have also observed that mechanical ventilation with high PEEP impedes lymphatic drainage and also cold increases the lymph production, while flow increased and lymphatic drainage of abdominal edema improved by spontaneous breathing (Lattuada 2006). Elias and co-workers in their ovine model found that endotoxin (i.v., 3.3 – 33 µg/kg) reduces lymphatic pump activity, contributing to the edema formation in sepsis (Elias 1987). Intrahepatic lymph stasis in endotoxaemia in rats can be caused by decreased pumping activity of extra- and intrahepatic large lymph vessels (Shibayama 1992). It has been showed in LPS-induced sepsis model in guinea pigs that there is an early increase in mesenteric lymph flow rate being mediated by vascular hyperpermeability and plasma albumin leakage (Nemoto 2011).

Microcirculatory and Mitochondrial Distress Syndrome

As described above, the excessive systemic reaction to the inflammatory insult finally leads to a critical imbalance of oxygen and nutritional products supply and demand. In the recent decade, it has been speculated that compensatory mechanisms in sepsis may be described as a 2-phase process. In the beginning, microvascular compensation dominates. During this phase, the decreased tissue perfusion and tissue hypoxia result in enhanced production of potent vasodilatory substances (mainly NO) (Gomez-Jimenez 1995). This reaction aims to increase the tissue perfusion. Whenever this compensation fails, in the second mitochondrial phase, cells are trying to turn into an “energy-saving mode” by decreasing their energy needs. The main actor in this process is again the overproduced NO. It passes easily through the cellular and mitochondrial membranes as oxygen and blocks cytochrome oxidase at complex IV. This compensatory mechanism however is a double-edged sword; although it decreases cellular energy need (and thus contributes to survival) but only until a certain limit: as a secondary consequence of complex IV block, reactive nitrogen species (most importantly peroxynitrites) are produced. Large amounts of reactive nitrogen species contribute to cell necrosis in severe, end-stage states of sepsis.

Multiple Organ Failure (MOF) in Sepsis

The continuum of sepsis is depicted in Figure 4. Based on the underlying pathophysiological mechanisms, different organs may be affected during the septic process (Albert 2004; Langenberg 2005; Remick 2007; Wynn 2010; Nduka 2011; Bhan 2016; Doi 2016).

- In the *cardiovascular system*, newly developing atrial fibrillation can be considered as early warning sign of developing sepsis. Beside this, decreased central venous and mean arterial blood pressures as well as a decreased peripheral vascular resistance are typical signs of septic cardiovascular affection. Cardiac contractility may eventually be higher in the early phase of sepsis, however, in the late phase of septic shock, cardiac contractility also decreases due to inappropriate oxygenation of the myocardium. Recent clinical observations suggest that PiCCO monitoring enables checking the cardiovascular consequences.
- *Pulmonary consequences*: Based on experimental and pathological observations, there is an inflammatory exudate accumulation within the alveoli. This exudate worsens the effectiveness of the alveolo-capillary gas exchange. It contributes to the washout of the surfactant, thus leading to alveolar collapse and atelectasis formation. Additionally capillary leak also affects the pulmonary capillaries and contributes to extravascular fluid accumulation within the lung. This extravascular lung water may lead to further compression of the alveoli (due to extraalveolar forces) and also leads to an increase of the alveolo-capillary distance that worsens gas exchange. The most sensitive parameter that describes the function of the alveolo-capillary gas exchanges is $\text{PaO}_2/\text{FiO}_2$ ratio. Extravascular lung water can be measured by PiCCO monitoring (EVLW).
- *Consciousness disturbances* of different severity are early signs of sepsis development. At early stages, sepsis causes confusions or delirious states. The correct terminology for the cerebral affection in sepsis is sepsis-associated encephalopathy. This is a multifactorially-determined functional disturbance that develops along with the progression of the septic process, leading to somnolence, or coma in late phases. Cerebral functions can be monitored by the GCS score and EEG.
- In early stages of systemic hypoperfusion, the urine output decreases and septic patients are prone to development of acute kidney injury. Along with the advancement of severe sepsis, oliguria may turn to anuria and serum creatinine progressively increases.
- Hypoperfusion of the liver has different consequences: albumin and vitamin K-dependent coagulation factor production decreases. In severe cases where parenchymal damage is advanced, bilirubin increases (by canalicular damage and hepatocytolysis) ($>70 \text{ mmol/l}$) and icterus may develop.
- Severe hypoperfusion also affects gastrointestinal organs. As a consequence, bowel ischemia, ileus, pancreas apoplexy and acalculous cholecystitis may develop.

Figure 4. The continuum of sepsis.

EXPERIMENTAL MODELS FOR STUDYING SEPSIS

According to Fink (2001), the ‘ideal’ animal sepsis model should be (1) capable of predicting both positive and negative results of a trial; (2) inexpensive; (3) reproducible (within and among laboratories); (4) humane and fully respecting the 3Rs; (5) able to provide a mortality endpoint; (6) characterized by hemodynamic, hematologic, and biochemical features similar to those observed in human sepsis (Fink 2001). Unfortunately there is no ‘ideal’ model known to date.

Experimental sepsis can be induced via generating toxemia by intravenous or intraperitoneal administration of live bacteria (pure or mixed cultures), inhalation, intrabronchial instillation, implantation or seeding into tissues or by disruption of the host-barriers (mechanically or by ischemia), or in combination. Behind these major approaches to develop sepsis models, there are numerous variations and sub-models that can be classified in the following main categories:

- endotoxin models
- bacteremia models
- peritonitis models
- pneumonia models
- meningitis models
- soft tissue infection models (abscess models)

Table 4 summarizes some major characteristics of these models. Each of these strategies reproduces one or several pathophysiological mechanisms activated during sepsis, yet the

multitude of existing approaches indicate limitations of each model to mimic the clinical scenario. Many of the limitations depend on the species of animals or bacteria used while others depend on technical and conceptual details behind each model.

Not only the way of sepsis induction, but the choice of the animal species itself is also crucial. Table 5 gives a summary of various species in consideration of sepsis models (based on Fink 2001).

Following sections provide the technical description of the methods for inducing experimental sepsis as well as brief considerations on their advantages and limitations.

Endotoxin Models

Endotoxin is a lipoprotein-carbohydrate complex that can be found in the cell wall of all gram-negative bacteria. Endotoxins were originally isolated by André Boivin (*Bactéries et Virus*, Paris, Presses Universitaires de France, 1941).

The simplest way is to inject single bolus of LPS intravenously (as the most common way) or intraperitoneally. The pro-inflammatory processes occur suddenly and last briefly when endotoxemia is induced by LPS injection (single bolus). Endotoxin can be administered via intraperitoneal injection as well (Laschke 2007). In case of infection, the inflammatory stimulus is much more obvious with gradual development and persisting longer. It has been shown that TNF- α concentration is much higher and showing a peak around 60-90 minutes after LPS injection (i.v. or i.p.) compared to a focal infection model (e.g., fecal peritonitis) (Eskandari 1992; Fink 2001). After endotoxin administration, plasma concentration of host response mediators such as TNF- α , IL-1, IL-6 and IL-10 rapidly increase as an acute and transient elevation. LPS binds to TLR-4 and so activates inflammatory pathways, including NF- κ B.

The sensitivity of various animal species to LPS and the physiologic and immunologic response to this stimulus is different. Humans are very sensitive to LPS; in volunteers 2–4 ng/kg LPS may produce obvious symptoms. In mice 1–25 ng/kg LPS is needed to generate septic symptoms. A very interesting study aimed at reaching a similar IL-6 response in mice and humans revealed that 2 ng of endotoxin administered intravenously in humans were enough to elicit the same IL-6 plasma levels as 500 ng given intraperitoneally to mice (Copeland 2005). Other species such as rabbit, pig and sheep are also sensitive to endotoxin, similarly to human. Interestingly, the rodents or even monkeys such as baboons are resistant to endotoxin. About 5 μ g/kg LPS is lethal in sheep, 100 μ g/kg is the LD₈₀ in rabbits, while mice and baboons needs incomparably higher dose for lethality (LD₇₀ dose is about 6 mg/kg in baboon; LD₁₀₀ dose is about 20–80 mg/kg in the mouse) (Fink 2001). Overall, endotoxemia models are relatively far from the clinical sepsis scenario. Furthermore, the resistance of rodents to LPS also puts a serious limitation of extrapolating the results to the human (Kingsley 2016).

There are several techniques and materials for increasing the sensitivity of rodents to LPS such as D-galactosamine, a non-ionic polyoxyethylene-polypropylene copolymer (Pluronic F127), carageenan, beryllium phosphate, lead acetate or carbon tetrachloride. Administration of platelet-activating factor or heat-killed bacteria a week prior to LPS injection can also cause enhanced sensitivity (Katschinski 1992; Rabinovici 1993; Fink 2001; Gumenscheimer 2002).

Rittirsch and co-workers reported in their paper that the LPS endotoxemia differs from cecal ligation and puncture (CLP) model in rodents. After LPS infusion, the symptoms such as rapid hypothermia developed within a few hours, together with leukopenia followed by leukocytosis. The scenario is also characterized by an early increase and high transient levels of pro-inflammatory cytokines (IL-1 β , TNF- α , IL-6) and the protective effect of anti-TNF- α is shown. In CLP model, the symptoms developed within 12–24 hours, leukocytosis or leukopenia was also present, whereas, the pro-inflammatory cytokines (IL-1 β , TNF- α , IL-6, C5a) were expressed later at moderately high levels. Anti-LPS or anti-TNF- α were not protective (Rittirsch 2007).

Intravenous, intraperitoneal or intraarticular administration of zymosan (a polysaccharide cell wall component derived from *Saccharomyces cerevisiae*), producing a prolonged activation of the alternative complement pathway and generalized inflammation, is another example for endotoxaemia models, mostly in rodents (mouse, rat) and rabbit (Sharkey 1984; Volman 2005; Cash 2009; Guerra 2016; Hong 2016;).

Bacteremia Models

Intravenous administration of live *Escherichia coli* is used for studying sepsis since decades. The early studies used typically large animals (dogs, pigs, monkeys) (Guenter 1969; Cryer 1971; Hinshaw 1976; Wichterman 1980). Later, rodent usage has been also spread out widely. Contrary to the rapid bolus infusion, which results in rapid hypoglycemia and death, further models have been established to provide more time for the response reactions approaching closer to the clinical scenarios. Postel et al. developed a canine model in which the animals were continuously infused with *Pseudomonas aeruginosa* for 5 hours (10⁶/ml/min for 2–5 hours or 4x10⁷/ml/min for 5 hours), and observed the animals for 24 hours. This model provided more time for developing wider response reactions and for observation of kinetics (Postel 1975).

In sepsis models with bacterial infusion, the exact number of bacteria can be estimated only that might influence the reproducibility compared to the better standardized endotoxin infusion models (Fink 2001). The most commonly used bacteria are the gram-negative *Escherichia coli*. Other gram-positive bacteria, such as *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pyogenes* or *Pseudomonas aeruginosa*, or fungi such as *Candida albicans* can be also used in various animal species (mouse, rat, rabbit, dog, pig, sheep, baboon).

PERITONITIS MODELS

The surgical models are particularly relevant models of sepsis since a significant number of sepsis cases are the result of intraabdominal leakage of intestinal content after abdominal surgery or perforated diverticulitis or appendicitis (Browne 1976; Wichterman 1980; Krisher 2001; Wryzykowski 2005; Catry 2016). These models generate a polymicrobial sepsis which closely resembles the clinical situation in terms of mechanism and clinical course. The

peritonitis may be induced by perforating the bowel or by instillation of bacteria or fecal material in the peritoneal cavity.

Cecal Ligation and Puncture (CLP)

This simple and reproducible model has become a gold standard in sepsis research because of its relative technical simplicity and versatility (Wichterman 1980; Hubbard 2005; Dejager 2011; Toscano 2011; Schabbauer 2012; Siempos 2014). Nonetheless, ensuring reproducibility requires that a few important details should be carefully considered throughout the procedure including preoperative fasting of the animals to generate similar intestinal contents as well as consistency in several other technical details. In addition, short-acting methods of anesthesia (i.e., isoflurane inhalation) should be chosen in order to minimize prolonged anesthesia-induced cardiovascular alterations postoperatively (Hubbard 2005). Following midline incision, the cecum is identified and carefully exteriorized. Then, the cecum is ligated distal to the ileocecal valve and perforated using one or two needle punctures (Figure 5). Both the length of the ligated cecum (Singleton 2003) and the needle size (Ebong 1999; Otero-Anton 2001) can be used to influence the CLP outcome and give a lethal or nonlethal sepsis. For instance, two punctures created with an 18G needle result in 100% mortality in BALB/c mice, while the same procedure yields mortality rates of 50% or 0% when performed with 21G or 25G needles, respectively (Ebong 1999).

The cecum is gently compressed to expel a small amount of intestinal content through the perforation, thereafter is returned to the abdomen and the wound is closed in two layers. The cecum will become necrotic within 24 hours but it may ultimately be resected to remove the source of infection as part of the treatment strategy.

Figure 5. Cecal ligation and puncture (CLP) in anesthetized rat. White arrow shows the site of the ligature. The excluded cecum punctured through by a 19 G needle.

The postoperative care is a significant element of this particular experimental model as fluid resuscitation and antibiotic treatment may influence significantly both the pathophysiology and animal survival (Zanotti-Cavazzoni 2009). In the rat, this model induces a complex cardiovascular response with an early, hyperdynamic phase characterized by increased cardiac output, increased tissue perfusion and decreased peripheral resistance. This is followed by a late, hypodynamic phase characterized by reduced microvascular blood flow

in various tissues and increased peripheral resistance (Yang 2002; Yang 1999). Results in mice and rats indicate that fluid resuscitation (typically isotonic saline as subcutaneous injection) and antibiotics may increase the 48 hour survival rate from 0 to around 20–40% (Hollenberg 2001) depending on type of fluid, volume and concentration (Zanotti-Cavazzoni 2009).

Colon Ascendens Stent Peritonitis (CASP)

The model of colon ascendens stent peritonitis (Zantl 1998) is more recent than the previously described CLP and has been introduced following numerous observations that animals undergoing cecal ligation and puncture often develop only localized peritonitis (Schabbauer 2012). The cecal perforations are spontaneously covered by the surrounding intestinal loops leading to abscess formation (Maier 2004). This in its turn may result in two different pathologic conditions not entirely comparable (diffuse peritonitis vs. large abscess) and with different response to various treatment alternatives.

The surgery is preceded by the preparation of plastic venous catheters of variable sizes. In the rat model, the survival rate is strictly dependent on the diameter of the implanted stent and a stent diameter of 14G leads to 100% mortality whereas smaller stent diameters generates sublethal models (16G stent leads to a 71% mortality whereas mortality is 53% when a 18G stent is used) (Lustig 2007). Similarly, approximately 70% of the mice expired within 48 hours when a 16G stent was used whereas the death rate dropped to 50% with an 18G stent (Maier 2004). After creating a marking at a distance of 3 mm from the tip, the catheter is circumferentially incised with a 1 mm scalpel beyond the marking sparing only a narrow bridge of plastic.

Inhalational anesthesia is advocated by the majority of the authors (ether, isoflurane, sevoflurane) (Lohner 2013; Islam 2016; Schöneborn 2016) due to the lower impact on the hemodynamics as well as the short postoperative recovery. The abdominal wall is opened through midline incision and the ascending colon is exposed using soft cotton earbuds. After adequate exposure of the ascending colon, the prepared catheter is inserted into the lumen of the ascending colon through the antimesenteric wall approximately 10 mm from the ileocecal valve and fixed with two stitches of non-absorbable suture (7/0) (Figure 6). Thereafter, the inner needle of the stent is removed and the stent is cut at the marked site. To verify the adequate intraluminal placement of the stent and the immediate initiation of the fecal leakage, stool is milked from the cecum into the ascending colon and the stent is filled until a small drop of stool appears at its end. The procedure is completed through abdominal wall closure in two layers and fluid resuscitation (Zantl 1998).

Bacterial Suspension Inoculation (Intraabdominal Abscess Models)

Classic models include the inoculation of defined bacterial isolates (e.g., *E. coli*, *B. fragilis*) mixed with barium sulfate and autoclaved rat fecal material, suspended and loaded into gelatin capsule and implanted intraperitoneally, or agar pellets containing bacteria, or suspension containing hemoglobin, mucin and bacteria (*E. coli*), or impregnated fibrin clot (Onderdonk 1976; Wichterman 1980; Fink 2001; Kingsley 2016). Inoculation of autologous

feces and other clinically-relevant model dominantly in pigs (for instance simulating the case of bowel anastomosis insufficiency), in which a definitive amount (e.g., 0.5 g/kg) of autologous feces is suspended in saline solution (e.g., 200 ml), incubated (e.g., for 6 hours at 38°C) and inoculated into the peritoneal cavity through drains, or via incision and/or Veres needle (Chvojka 2008; Zsikai 2012) (Table 6).

Interventions that Partly Destroy Barriers of Gastrointestinal Tract

Intestinal ischemia models. An example is the creation of an ischemic bowel loop results in severe diffuse peritonitis (Wichterman 1980). Hau and Simmons (1977) and which reported 90% mortality rate within 10 days after making a loop of terminal ileum ischemia in dogs. Simpler intestinal ischemia-reperfusion models with longer follow-up period, allowing time for development of symptoms, are also capable for mimicking abdominal sepsis.

Cholecystitis models. In the canine study of Perbellini and co-workers, *E. coli* was injected directly into the gall bladder after ligating the cystic artery. The ischemic and infected gall bladder showed similarities to clinically seen cholecystitis (Perbellini 1978; Wichterman 1980).

Pneumonia Models

In this simple and clinically relevant model type, *Streptococcus pneumoniae*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa* are the most common bacteria which are introduced via a tracheal route (tube in rodents, or even with bronchoscope in large animals), or via nasal route (Fink 2011; Kinglsey 2016).

Figure 6. Colon ascendens stent peritonitis (CASP) in anesthetized rat. White arrow shows the fixed stent (size: 16 G).

Meningitis Models

Several murine models have been developed using intracerebral, intraperitoneal, intravenous, intranasal or intracisternal inoculation methods (Chiavolini 2008). In the latter category, a well-established model is inoculation by injecting 10 µL of bacterial suspension into the cisterna magna using a 32 G needle (Mook-Kanamori 2012; 2015).

Meningitis in rats can be produced by intranasal inoculation of *Haemophilus influenzae* in newborn rats, or in young adult animals by intraperitoneal inoculation (Smith 1984).

Streptococcus pneumoniae is also used for meningitis models. Intraperitoneal route provokes hematogenous meningitis. The intranasal inoculation can act non-hematogenously as well along the olfactory nerves (Chiavolini 2008).

Soft Tissue Infection Models (Abscess Models)

Intramuscular abscess models. Hermreck and Thal (1969) described a model in which 5-cm wicks of umbilical tape were seeded with the dog's own feces and immersed into porcine mucin solution. These wicks then were embedded into the thigh (unilaterally) of the dog subcutaneously and intramuscularly. The animals were followed-up for a week.

Dermal abscess models. In 1964, Walker et al. published a rat model mimicking dermal abscess. *Pseudomonas aeruginosa*, isolated from a patient with septicemia after second and third degree burn injury, was used to seed subcutaneous tissues. On the dorsum, a 5×7 cm area was excised (~20% of the body surface), and the fascia in the base of the wound was seeded by the bacterial culture. The area then was covered with split-thickness (0.012 inch) skin autograft. In their study, a comparison was made with intraperitoneal and subcutaneous injection of the bacterial culture as well (Walker 1964).

Intramuscular, subdermal bacterial injections, subcutaneous pockets filled with gauze and injected bacteria, infected cotton suture are further examples for soft tissue infections models (Fink 2001).

EXTRAPOLATION OF THE RESULTS: EXPERIMENTAL VERSUS CLINICAL SEPSIS

The final goal of all medical research is and must be the benefit to the patient, by exploring and understanding the nature of various disorders and its pathophysiology mechanisms as well as developing preventive or therapeutic agents. In this process, animal studies are still necessary, since in the translational process, there must be a stage of *in vivo* study before any human application.

Unfortunately, numerous pharmacological agents which have been promising and effective in animal models, failed in large well-designed human clinical trials (e.g., methylprednisolone sodium succinate, IL1-RA, CDP571, BN 5021, BB-822, TCV-309, TAK-242, lenercept, tifacogin) (Fink 2014; Lakshmikanth 2016).

Practically speaking, all the experimental sepsis models fail to reproduce entirely the clinical scenario. This explains the relatively large number of models used to induce severe systemic infections and continuous search for a better mirror to the clinical situation. Accordingly, numerous authors have discussed the comparability of animal sepsis models and human sepsis (Wichterman 1980; Fink 2001; Esmon 2004; Rittirsch 2007; Nemzek 2008; Poli-de-Figueiredo 2008; Dyson 2009; Fink 2014; Lilley 2015).

In the clinical practice, the most frequent infection sites are the lung, the abdomen and urinary tract. Gram-positive and gram-negative infections show almost the same frequency, followed by fungi and parasites. The initial insult or infection activates the innate immune system bursting the pro-inflammatory cascades and mediators with SIRS as result. Anti-

inflammatory factors appear as compensatory mechanism but any imbalance can cause further deterioration: exaggerated pro-inflammatory effect results in uncontrolled, excessive inflammatory response and consecutive effects; stronger anti-inflammatory steps may lead to immunosuppression (Rittirsch 2007).

Virtually all the experimental sepsis models in rodents fail to reproduce entirely the clinical scenario due to limitations related to design or the species used. Moreover, seemingly minor technical details (Ebong 1999; Singleton 2003) or the choice of the animals used in terms of age and gender impacts on the pathophysiology and the outcome (Turnbull 2003). Compared with humans, rodents are quite resistant to endotoxin, have a distinct hemodynamic profile, and limited blood volume (Copeland 2005). All these factors explain the relatively large number of models used to induce severe systemic infections and the ongoing search for refined designs to better mirror the clinical situation.

Microbiological Actors Causing Sepsis

In human sepsis, gram-positive bacteria and fungi act for causing sepsis in higher incidence than gram-negative organisms, however, in animal studies mostly gram-negative bacteria have been used (Poli de Figueiredo 2008).

Experimental Considerations Related to the Pathomechanism of Sepsis

In clinical scenario, usually there is a septic focus which intermittently or persistently scatters bacteria. Different ways of sepsis induction act differently, as it has been discussed previously and overviewed in Table 4.

The Time Factor (Follow-Up)

For development of sepsis, time is needed that differs according to the way of induction (Table 4). Endotoxemia and infusion of bacteria provide prompt effects, while infection site models obviously need more time to develop the response reactions and the septic symptoms. The choice of the model depends on the primary aim of the study itself.

Inter-Species Differences in Sensitivity and Immune Response

Several inter-species differences have been discussed in previous sub-sections. To list some other ones, it is interesting to mention that *Salmonella typhi* does not cause systemic infection in rodents, but causes typhoid fever in humans. *Salmonella typhimurium* causes systemic infection in rodents, but has low virulence in humans (Piper 1996; Poli de Figueiredo 2008).

Table 4. Summary of various septic models by its nature, origin, most commonly used species, advantages and disadvantages (based on papers by Fink 2001; Esmon 2004; Volman 2005; Rittirsch 2007; Poli de Figueiredo 2008; Engel 2011; Mai 2012; Fink 2014; Kingsley, 2016)

Sepsis origin	Model	Species	Characteristic hemodynamic response	Persistent inflammatory response	Cytokine response characteristics	Advantages	Disadvantages	Special notes
Toxemia	Endotoxin (LPS) administration	<i>Most commonly used:</i> mouse, rat <i>More rarely used:</i> rabbit, dog, pig, sheep, non-human primates	immediate early hypodynamic phase	no	Early rise of TNF- α , rapid transient increase	Easy model. LPS dosage is well-controllable. Innate immune system activation can be well studied. Well-suited to test the mechanism of inflammatory cascade activation and the efficacy of anti-inflammatory compounds.	Far from clinical scenario. Different sensitivity amongst the species (relatively endotoxin resistant species: rodents, cat, dog; sensitivity with enhanced response: rabbit, sheep, non-human primates). Dose dependency (concentration and way of administration)	Toxin can be given: i.v., i.a., i.p. LPS effect can be enhanced by administration of D-galactosamine, pluronic F 127, carageenan, lead acetate, beryllium phosphate, carbon tetrachloride, platelet-activating factor, co-administration of heat-killed bacteria (e.g. <i>P. acnes</i> , <i>C. parvum</i> , <i>M. bovis</i>), mostly in rodents.
	TLR agonist administration (i.v.)	rodents	Not specified.	no	Rapid immune activation and inflammation, elevation of IL-6 and IFN- β within 2 h	Technically easy model.	Nonspecific indicator of inflammation, short half-time of agents, immunological effects often controversial	Mostly TLR-9, TLR-7, TLR-3 agonists
	Administration of zymosan	rodents (most frequently rabbits), rarely in sheep	early drop in cardiac index and stroke volume index	no	Prolonged activation of the alternative complement pathway, generalized inflammation	Easy to perform. Can be used for studying sterile peritonitis, MODS and acute lung injury as well.	Early mortality rate is high.	Toxin can be given: i.v., i.a., i.p., intraarticularly. Acute inflammation peaking within few hours. Marked hypoxaemia, interstitial edema, pulmonary neutrophil sequestration.

Table 4. (Continued)

Sepsis origin	Model	Species	Characteristic hemodynamic response	Persistent inflammatory response	Cytokine response characteristics	Advantages	Disadvantages	Special notes
Bacteremia	Intravascular infusion of live bacteria	rodents, dog, pig, sheep, non-human primates	hypotensive shock	no	Rise of TNF- α and IL-1 β , rapid transient increase	DIC presents.	Relatively far from clinical scenario.	Most commonly used bacteria: <i>E. coli</i> Others: <i>S. aureus</i> , <i>P. aeruginosa</i> , <i>S. pyogenes</i> , <i>S. epidermidis</i> , <i>C. albicans</i> Variations: Bolus (single or multiple), increasing concentration via infusion pump.
Peritonitis	cecal ligation and puncture (CLP)	most commonly rodents	hemodynamic and metabolic phases	yes	moderate increase	Clinically highly relevant.	Not specified.	-
	colon ascends stent peritonitis (CASP)		prolonged hemodynamic instability	yes	steady, continuous systemic increase	Clinically highly relevant. Lethality is accompanied by MOF.	Not specified.	-
	polymicrobial peritoneal contamination and infection (PCI)		early hyperdynamic response	yes		Clinically highly relevant.	Not specified.	e.g., intraperitoneal injection of a human feces suspension
	implantation model (implanting fibrin clot impregnated with live bacteria)	rat dog, pig		yes	Similar to human sepsis.	Clinically highly relevant.	Not specified.	Most commonly used bacteria: <i>E. coli</i> Others: <i>B. fragilis</i> in combination with <i>E. coli</i>

Sepsis origin	Model	Species	Characteristic hemodynamic response	Persistent inflammatory response	Cytokine response characteristics	Advantages	Disadvantages	Special notes
	faecal peritonitis (inoculation of autologous faeces or faecal suspension)	pig	early hyperdynamic response	yes	Similar to human sepsis.	Clinically highly relevant.	Not specified.	-
Pneumonia	Direct administration of bacteria (<i>S. pneumoniae</i> , <i>P. aeruginosa</i> , <i>K.pneumoniae</i>) via trachea or nasal route	mouse, rat	absent	yes	Strain-specific (e.g. TNF- α decrease after <i>S. pneumoniae</i> infection)	Clinically relevant.	Not specified.	-
	Instillation of living bacteria into bronchi via bronchoscope	pig	Not specified.	yes	Not specified.	Clinically highly relevant.	Not specified.	-
Soft tissue infection	Injecting bacteria or implanting contaminated materials into soft tissue	rodents, dog	Not specified.	yes	Not specified.	Clinically relevant.	Not specified.	Intramuscular, subdermal bacterial injections, subcutaneous pockets filled with contaminated gauze or cotton suture
Meningitis	Inoculation of bacteria (intracerebral, intraperitoneal, intravenous, intranasal, intracisternal)	mostly rodents	Not specified.	yes	Strain-specific.	Clinically relevant.	Not specified.	Most commonly used bacteria: <i>H. influenza</i> , <i>S. pneumoniae</i>

Table 5. Summary of advantages and disadvantages of various animal species in sepsis studies (based on Fink 2001, with additions and modifications)

Species	Advantages	Disadvantages
mouse (<i>Mus musculus</i>)	inexpensive, inbred or transgenic strains available, immunological reagents widely available	repetitive blood sampling is difficult, problematic hemodynamic measurements – special instruments needed, moderately resistant to LPS
rat (<i>Rattus norvegicus</i>)	inexpensive, inbred, outbred or transgenic strains available, immunological reagents widely available, most hemodynamic measurements feasible, chronic instrumentation feasible, faecal flora shows certain similarities to that of human	very resistant to LPS
guinea pig (<i>Rattus norvegicus</i>)	inexpensive, various outbred strains available, immunological reagents available, most hemodynamic measurements feasible, chronic instrumentation feasible, very sensitive to LPS	gram-positive faecal flora, coprophagy (caecotrophia)
rabbit (<i>Oryctolagus cuniculus</i>)	inexpensive, most hemodynamic measurements feasible, chronic instrumentation feasible, very sensitive to LPS, septic acute lung injury reminiscent of human ARDS	gram-positive faecal flora, caecotrophia
sheep (<i>Ovis aries</i>)	relatively inexpensive for a large animal, faecal flora similar to that of human, well-suited for hemodynamic measurements, repetitive blood sampling and chronic instrumentation, septic acute lung injury reminiscent of human ARDS – so good for studying pulmonary pathophysiology, very sensitive to LPS, often are used in chronic, examples for unanesthetized models	chronic study is difficult
pig (<i>Sus scrofa domestica</i>)	relatively inexpensive, renal, cardiovascular and digestive anatomy and physiology as well as faecal flora close to human, well-suited for hemodynamic measurements and repetitive blood sampling, septic acute lung injury reminiscent of human ARDS, relatively sensitive to LPS	chronic study is difficult (acute or subacute models only)
cat (<i>Felis catus</i>)	well-suited for hemodynamic measurements and repetitive blood sampling, but not a typical species for sepsis study rather for research on central nervous system	heightened public concerns as companion animal
dog (<i>Canis familiaris</i>)	faecal flora similar to that of human, well-suited for hemodynamic measurements and repetitive blood sampling, chronic instrumentation feasible	heightened public concerns as companion animal, moderately resistant to LPS, relatively expensive, portal venous hypertension after endotoxic challenge
nonhuman primates, e.g., baboons (<i>Papio doguera</i> , <i>Papio anubis</i> , <i>Papio cynocephalus</i> , etc.), cynomolgus macaque (<i>Macaca fascicularis</i>), rhesus macaque (<i>Macaca mulatta</i>)	well-suited for hemodynamic measurements and repetitive blood sampling, antibodies against human proteins commonly cross-react, studies to closely replicate the human inflammatory response	heightened public concerns, very expensive, chronic instrumentation difficult, very resistant to LPS, potential zoonotic disease transmission

The evolutionary adaptation and environmental factors have rendered rodents much less sensitive to bacterial products including endotoxin, as discussed previously. In addition to that, rodents usually react to endotoxemia differently than humans. Cecal ligation and puncture in the rat elicits a biphasic cardiovascular response. An early hyperdynamic phase is usually found during the first 6 hours, and it is characterized by increased cardiac output and tissue perfusion, increased oxygen delivery and oxygen consumption as well as decreased peripheral resistance (Wang 1996; Yang 1999). If inadequately resuscitated, these are replaced by a late, hypodynamic phase towards the end of the first 24 hours after the initiation of sepsis. This late phase is characterized by reduced microvascular blood flow in various tissues, decreased oxygen delivery and increased peripheral resistance. These changes are the key events leading to the development of MOF and ultimately to death. Besides a different cardiovascular response, the immunologic response in rodents differs from humans. A murine study reported similar outcome (mortality and morbidity) but significant differences in the kinetics of cytokine production. Thus, TNF- α usually peaks at 1–2 hrs after endotoxin challenge in both rodents and humans but normalizes by 4 hrs and 2.5–10 hrs, respectively (Remick 2000).

Normovolemic septic patients typically present increased cardiac output, hypotension, decreased peripheral resistance and oliguria. In dogs, for instance, the endotoxemia is associated with hypotension but with increased peripheral resistance (Wichterman 1980; Kaszaki 1997). The differences between animal species in response to living bacteria infusion can be different. For instance, *E. coli* may cause either hypodynamic or hyperdynamic circulatory response (Fink, 2001).

Concerning species-specific differences, it is important to mention that pigs and sheep may express marked pulmonary hypertension and increased pulmonary endothelial permeability and other characteristics of acute lung injury after injection of endotoxin or gram-negative bacteria. The reason is that the pulmonary intravascular macrophages (PIM) are embedded within the endothelial lining of pulmonary arterioles (Traber 1978; Judges 1986; Fink 2001).

In a chronically instrumented pig model, Haberstroh and co-workers used a relatively low dose of viable *P. aeruginosa* for 84 hours. They found triphasic hemodynamic response: (1) pulmonary hypertension and decrease in cardiac output (0–12 hours), (2) normalization (12–60 hours), and (3) secondary rise in pulmonary arterial pressure, systemic artery hypotension and increased cardiac output (60–84 hours) (Haberstroh 1995; Fink 2001).

Effect of Age, Gender, and Co-Morbidities

Age is an important issue both in clinical and experimental scenarios (Watters 2001; Starr 2014). In most of the experimental models, the animals are usually young adults and healthy animals, without co-morbidities. Agent is a toxin or a defined type of micro-organism. The treatment protocol (if any) is standardized and initiated soon after the onset of sepsis. The animals are usually anesthetized. Coprophagy is common.

Table 6. Methodological summary of some selected recent sepsis studies in pigs with different sepsis induction methods and various anesthesia protocols and observation periods

Strain, Sex, Weight	Method of inducing sepsis	Protocol	Anesthesia, drugs, fluid administration	Other related interventions	Duration of observation	Reference
domestic outbred stock, either sex, 15 kg	LPS i.v.	Ultrapur <i>E. coli</i> LPS (strain 0111:B4) dissolved in sterile water. A total amount of 0.03 mg LPS/kg was infused intravenously over 30 min.	ketamine (20 mg/kg), atropine (0.4 mg) and azaperone 40 mg/ml (1.5 ml), i.m., isoflurane (end tidal cc: 1%), morphine, 50-100 mg pentobarbital i.v., 1 mg/kg/h, i.v., mechanical ventilation (PEEP=5 cmH ₂ O, FiO ₂ =0.3), Ringer acetate, 8 ml/kg/h	preparation and cannulation of external jugular vein l.d., carotid artery l.d., pulmonary artery catheter, tracheostomy, urinary bladder catheter via skin incision	6 hours	Thorgersen 2010
domestic outbred stock, either sex, 15 kg	living bacteria i.v.	Live <i>E. coli</i> (strain LE392; ATCC 33572) infused intravenously at an increasing rate: 3.75 × 10 ⁷ bacteria/h from 0 to 60 min, 1.5 × 10 ⁸ bacteria/h from 60 to 90 min, and 6.0 × 10 ⁸ bacteria/h from 90 to 240 min			6 hours	Thorgersen 2010
domestic outbred stock, either sex, 25-35 kg	living bacteria i.v.	Live <i>E. coli</i> (strain LE392; ATCC 33572) 1.5x10 ⁹ /ml infused intravenously at an increasing rate. In low dose: total of 4x10 ⁹ bacteria, increase from 4 ml/h after 60 min to 16 ml/h after 90 min, thereafter constant. In high dose: total of 16x10 ⁹ bacteria, increase from 4 ml/h after 30 min to 16 ml/h after 60 min, to 64 ml/h after 90 min, thereafter constant.			3 hours	Castellheim 2008
domestic outbred stock, either sex, 25-35 kg	living bacteria into the bronchus	Live <i>E. coli</i> (strain LE392; ATCC 33572) 20 ml of 1.5x10 ⁹ /ml suspension instilled into each main bronchus via a flexible bronchoscope			5 hours	Castellheim 2008
domestic outbred stock, females, 16-18 kg	living bacteria i.v.	<i>Escherichia coli</i> suspension (2.5x10 ⁷ /ml; strain: ATCC 25922,) infused intravenously at an increasing rate: 2 ml in the first 30 min, then 4 ml in 30 min and afterwards 16 ml/h for 2 hours. A total of 9.5x10 ⁶ <i>E. coli</i> within 3 hours	Induction: i.m. 15 mg/kg ketamin and 1 mg/kg xylazin, maintenance i.m., pressure support mechanical ventilation (Pa O ₂ : 100–130 mmHg, PaCO ₂ : 35–45 mmHg).	preparation and cannulation of external jugular vein l.s. (thermodilution sensors, pressure monitoring, blood sampling, fluid and anesthetic drug intake), femoral artery l.s. (thermodilution sensors, pressure monitoring, blood sampling) (tracheostomy inferior (assisted ventilation))	8 hours	Nenneth 2015

Strain, Sex, Weight	Method of inducing sepsis	Protocol	Anesthesia, drugs, fluid administration	Other related interventions	Duration of observation	Reference
domestic outbred stock, either sex, 27–35 kg	faecal peritonitis (autologous faeces inoculation)	0.5 g/kg of autologous faeces suspended in 200 ml saline was inoculated into the peritoneal cavity through drains.	Induction: i.v. 0.5 mg atropine, 1 to 2 mg/kg propofol 2% and 2 mg/kg ketamine. Mechanically ventilation (PEEP=10 cmH ₂ O, FiO ₂ =0.4, tidal volume: 10 ml/kg) Surgical anaesthesia: intravenous 5–10 mg/kg/hour thiopental and 5–15 µg/kg/hour fentanyl. Pancuronium (4 to 6 mg/hour), infusion of Plasma Lyte solution (7–15 ml/kg/hour), 20% glucose to maintain blood glucose levels between 4.5 and 7 mmol/l.	central venous and pulmonary artery catheters, external jugular vein and femoral artery cannulation. Midline laparotomy, drainage, urinary bladder catheterization via epicystostomy.	22 hours (after 8 hours of stabilization)	Chvojilka 2008
Vietnamese minipig, either sex, 24 ± 3 kg	faecal peritonitis (autologous faeces inoculation)	0.5 g/kg of autologous faeces suspended in 200 ml saline was incubated for 6 hours at 38 °C, then the suspension was intraperitoneally inoculated via a small incision above the umbilical scar and through a Veres-needle.	Anesthesia for sepsis induction: i.m. 20 mg/kg ketamin and 2 mg/kg xylazin, then 6 mg/kg/h i.v. propofol. After the induction process, animals were sedated and analgesic was used (4 mg/kg ketamin, 0.6 mg/kg nalbuphin). 15 hours later the animals were re-anaesthetized for invasive monitoring. Ringer-lactate 15 ml/kg/h, Voluvel 6% 130 kDa/0.4 5 ml/kg/h, and in case of need: 0.015 µg/kg/h i.v.	Unilateral preparation and cannulation of external jugular vein (pressure monitoring, sampling, infusion). Endotracheal intubation. Unilateral preparation and cannulation of femoral artery and vein (thermodilution sensors, pressure monitoring). Urinary bladder catheterization via inguinal incision.	24 hours (measurements started 15 hours after sepsis induction)	Zsikai 2012

In humans, sepsis often is seen at extreme ages (neonates or elderly), the origin is more often an infection site usually not recognized or frequently, the infection is polymicrobial. The treatment is initiated usually late (hours or days) after the start of infection and frequently the antibiotics are ineffective and are very different between cases. The presence of the co-morbidities is increasingly common (atherosclerosis, hypertension, diabetes mellitus, cancer, etc.) (Esmon 2004).

Gender differences have been also observed. Receptors for sex hormones have been identified on various immune cells, suggesting direct effects of these hormones on immune function (Albertsmeier 2014).

There are models with immunosuppressed host and so-called sequential challenge models. Co-morbidities can be induced by acute ethanol ingestion, CCl₄-induced cirrhosis, hemorrhagic shock, trauma, splenectomy, thermal injury, etc., mostly in rodents (Fink 2001).

Anesthesia, Drugs, Resuscitation

The clinical management of septic animals versus septic patients is a very important point of view, such as volume therapy, electrolytes, antibiotics, ventilation, etc. These protocols in experiments have unquestionable importance (Naumann 2015). Table 6 summarizes methodological details of some selected porcine sepsis models, which include the sepsis induction, the instrumentation, the anesthesia, drugs, resuscitation protocols as well as the follow-up periods are different.

CONCLUSION

Unfortunately, sepsis remains a severe clinical challenge with numerous unsolved problems. Animal models are both useful and necessary to explore the pathophysiology and develop effective therapeutic strategies. Nonetheless, besides their advantages, the experimental models of sepsis have numerous limitations that need to be considered when translating the experimental findings into clinical trials.

Some of the main factors have to be taken into consideration when planning, conducting and evaluating experimental sepsis models:

- the method of sepsis induction
- the agent (type of toxin or microorganism)
- choice of animal species
- species-specific characteristics in immune response sensitivity, in physiological and even anatomical features
- age and gender of the animals
- effect of anesthesia, drugs, fluid intake, resuscitation
- co-morbidities (absence or presence)
- duration of the follow-up (observation period)

In general it can be also concluded that small animal models (e.g., mouse, rat) are useful to test certain pathophysiological pathways and for developing/testing drugs, while large animal models (e.g., pig, non-human primates) may provide a better scenario for testing novel treatment strategies being closer to the clinical practice by size, physiology and opportunities for intervention.

Chapter 188

BARIATRIC EXPERIMENTAL SURGERY MODELS

Osman Bilgin Gulcicek*, MD

University of Health Sciences
Istanbul Bagcilar Training and Research Hospital,
Department of General Surgery,
Istanbul, Turkey

ABSTRACT

Obesity has recently become a major health problem. To treat obesity, there are non-surgical and surgical methods. However, surgical methods are more effective in managing obesity. Bariatric surgical methods are classified as restrictive, malabsorptive and combined methods. But sleeve gastrectomy and gastric plication are the most popular methods.

These techniques are easily applicable in clinic and have fewer complications. Both methods provide sufficient weight loss and decrease ghrelin and leptin levels. To plan an experimental surgery study for treating obesity, especially in small animals, these two techniques should be preferred for success of the experiments.

Keywords: obesity, sleeve gastrectomy, gastric plication, experimental

INTRODUCTION

Obesity is defined as accumulation of abnormal or excessive fat tissue leading to cardiovascular system diseases, diabetes mellitus, metabolic syndrome, musculoskeletal disorders and psychiatric problems. Obesity is recognized as a major health problem today (Ewing 2011; Blackburn 1987).

* Corresponding Author's Email: drosmanbilgin@hotmail.com; Fax: +90212 440 42 42.

The diagnosis of obesity is done by calculating body mass index (BMI; weight in kilograms divided by length in squared meters, kg/m^2). Patients with a BMI of over 40 kg/m^2 are considered morbidly obese (National Institutes of Health 2010).

To treat obesity, there are non-surgical modalities like diet, changes in habits and medical treatment. But these approaches have limited effects on weight loss (Lo´pez-NavaBrevie`re 2015). Additionally, these strategies are not affecting obesity continuously. However, surgery is considered to be effective in managing obesity (Benaiges 2015).

Bariatric surgery can be classified as restrictive (gastric plication, sleeve gastrectomy, adjustable gastric banding, intragastric balloon), malabsorptive (biliopancreatic diversion, biliopancreatic diversion with duodenal switch) and combined methods (Roux-en-Y gastric bypass, mini gastric bypass).

All these surgical procedures are conducted according to the recommendations of the American Society of Bariatric Surgery (Gastrointestinal surgery for severe obesity 1992).

Adjustable gastric banding was first applied in 1980s by Kuzmak. Gastric band is wrapped around the proximal stomach and there is a small gastric pouch on the upper side. This gastric band is connected to the port, placed under the skin through the catheter (Kuzmak 1991).

Intragastric balloon is a method which is based on inflating the balloon inserted into the stomach endoscopically and thus reducing the stomach volume (Benjamin 1988).

Biliopancreatic diversion was popularized first by Italian surgeon Scopinaro in 1979. This procedure reduces the duration of food interaction with digestive enzymes and absorption surface and abbreviates the transit time of food through the stomach.

It includes partial distal gastrectomy, transection of the small bowel approximately halfway between the ligament of Treitz and ileocecal valve, roux-en-Y gastroenterostomy and an anastomosis of biliopancreatic limb with the alimentary limb 50 cm before the ileocecal valve forming a common channel (Kamal 2012).

Biliopancreatic diversion with duodenal switch was described by Tom R. De Meester. It is actually an anti-reflux surgery. In this procedure, anastomosis is made between roux leg and first part of duodenum. So biliopancreatic diversion is modified by preserving pyloric sphincter (Alan 2008).

Roux-en-Y gastric bypass was developed from the weight loss that was observed in patients undergoing surgery (partial stomach resection and Billroth-2 anastomosis) for ulcers. Today, it is the most commonly used bariatric method in United States. It was performed as a loop bypass with a larger stomach. In this procedure, stomach is divided horizontally and jejunum is transected from 40–50 cm distal part of Treitz ligament. There is an anastomosis between distal jejunum and new gastric pouch. The other anastomosis is performed between the proximal jejunum and distal jejunum, 75–150 cm away from the first anastomosis. This prevents the bile reflux to the esophagus and new stomach pouch after the surgery (Mason 1967).

Mini gastric bypass was first developed by Robert Rutledge in 1997. It is a simplified form of roux-en-Y gastric bypass. In this procedure, a long narrow tube of the stomach along the lesser curvature is created. A loop of the small intestine is brought up and hooked to this tube at about 180–200 cm from the Treitz ligament (Rutledge 2001).

There are two important hormones in obesity surgery: Ghrelin and leptin. Ghrelin was discovered by Davis and described by Kojima in 1991.

It is expressed by specialized enterochromaffin cells located in the fundal region of the stomach. There is a proportional correlation between BMI and ghrelin decrease (Davis 1954; Kojima 2001).

Leptin is produced by adipocytes and secreted into blood. It is directly proportional with BMI and amount of body fat. Plasma leptin level is reduced in people who lose weight (Tadokoro 2015; Dagogo 1996). Decreasing plasma leptin and ghrelin levels by the operations of sleeve gastrectomy and gastric plication are shown in an experimental study (Gulcicek 2016). Sleeve gastrectomy and gastric plication have been performed with gradually increasing frequency in recent years. Both procedures can also be applied laparoscopically (Shen 2013).

Sleeve gastrectomy was first described in 1993 by Marceau et al. It was initially applied as a first stage of biliopancreatic diversion, duodenal switch and gastric bypass operations. Until 2003, it has been applied alone. It is a two-stage operation; dissection of the stomach and resection of the stomach. Greater curvature of the stomach is mobilized by the division of gastrocolic and gastrosplenic ligaments.

Figure 1. Sleeve gastrectomy.

Figure 2. Gastric plication.

This dissection should be extended to the left crus of the diaphragm for the complete resection of the fundus. The second stage involves resection of the greater curvature of the stomach from antrum to angle of His throughout latarjet nerve. About 2/3 of the stomach is removed with this surgery (Figure 1) (Marceau 1998). Two mechanisms are judged with the weight loss after sleeve gastrectomy: Mechanical restriction by reducing the volume of the stomach and a decline in appetite by subtracting the fundus where ghrelin is produced (Weiner 2007).

Gastric plication was first described by Taleppour and Amoli in 2007. In this technique, as in sleeve gastrectomy, gastrocolic omentum is divided and the short gastric arteries are dissected.

Then, greater curvature of stomach is plicated over itself by two layered continuous non-absorbable sutures with the help of 32–36 F plug catheters. By this way, the lumen of the stomach is reduced (Figure 2) (Talebpourand 2007).

The amount of ghrelin production is reduced in the fundus because of the dissection of short gastric arteries in gastric plication.

ANATOMY OF THE STOMACH IN RATS

General anatomical features of the rat stomach are similar to those of human stomach. It is located in the left side of the abdominal cavity as in humans and adjacent to the left lobe of the liver, esophagus, colon and spleen.

When observed with the naked eye, it consists of two main sections of different colors: Cutan section and glandular section (Figure 3).

Figure 3. Front view of the stomach of rat.

Cutan section forms the proximal part of the stomach; it is adjacent to the esophagus and its color is lighter. Cutan part is thin-walled and lined with keratinized squamous epithelium. It is responsible for storage and digestion of food. The section which constitutes the large part of the stomach is glandular section.

Glandular section is thick-walled and consists of columnar epithelium. In lamina propria of this section, there are pepsin and HCl secreting cells. This section continues to the duodenum and small intestine as in human (Barlow 2009).

HOW TO CREATE OBESE RATS?

For bariatric experimental surgery, obese rats should be used. Therefore we need to select the rats which are already obese or we need to create obese rats.

Standard diet of experimental animals includes 50% carbohydrates, 25% protein and 5% fat. If we use high-fat diet (35% carbohydrates, 20% protein and 45% fat; d12451, Research Diets, New Brunswick, NJ, USA) for about 28 days, we can get obese rats (Tuncer 2007).

Another method is that when we add 25 grams of butter into 100 grams of standard diet, we'll get diet containing 65% fat. Daily weights of animals are recorded. When the desired weight is reached, we could use these animals for experimental obesity models (XZhou 1998).

BARIATRIC SURGICAL MODELS OF THE RATS

All surgical procedures for obesity mentioned above can be applied to rats.

Figure 4. Sleeve gastrectomy on rat stomach.

Figure 5. Gastric plication on rat stomach.

For *sleeve gastrectomy*, 3 cm midline incision is done under sterile conditions. Gastrocolic and gastrosplenic ligaments and short gastric arteries are dissected from 0.5cm proximal to the pylorus to diaphragmatic crus. 50–70% of the stomach is excised. Then, the inner layer is closed by continuous 5/0 polypropylene sutures and the outer layer is closed with continuous extramucosal sutures by 5/0 polypropylene (Figure 4) (Gulcicek 2016).

For *gastric plication*, the same steps are done. Stomach is not excised. After the dissection of ligaments, plication of the greater curvature is done with two layered extramucosal continuous sutures by 5/0 polypropylene (Figure 5) (Gulcicek 2016).

After the operation, abdomen layers are closed duly and after 5 hours, all rats are fed ad libitum.

CONCLUSION

All surgical procedures for obesity mentioned above for humans can be applied on rats. However, gastric plication and sleeve gastrectomy are the most popular bariatric surgical methods used in recent years.

Technically, it is easier to apply these methods on small experimental animals and complication rates are much less than the other methods. The short operation time and optimal use of anesthetic agents increase the success rate of the experiments.

Chapter 189

ANIMAL MODELS OF HEART FAILURE

Mouer Wang*, MD

Cardiovascular Institute, Stanford University, Stanford, CA, US

ABSTRACT

Cardiovascular diseases (CVD) often lead to heart failure (HF). HF prevalence is continuously rising and represents one of the leading causes of death and an economic burden in the western societies. The study of potential novel therapeutic options and interventions requires reliable animal models to evaluate myocardial progressive structural and functional changes. Indeed, during the past 40 years, basic and translational scientists have used small animal models to understand the pathophysiology of HF and improve prevention and treatment of patients suffering from congestive HF (CHF). Each species and animal model has advantages and disadvantages and the choice of one model over another should take them into account for a good experimental design.

The aim of this chapter is to describe and highlight the features of some commonly used small animal (rats and mouse) surgical models of cardiovascular diseases leading to HF.

Keywords: heart failure, rat, mouse, left anterior descending (LAD) artery ligation, aortic banding, aorto-caval fistula (ACF)

ABBREVIATIONS

ACF	aorto-caval fistula
CHF	chronic heart failure
CVD	cardiovascular diseases
HF	heart failure
LAD	left anterior descending
LV	left ventricle

INTRODUCTION

Heart failure is a clinical syndrome characterized by cardiac dysfunction and myocardial structural abnormality (e.g., hypertrophy and dilated cardiomyopathy) resulting in inability of the heart to eject sufficient blood to the metabolizing tissues. Heart failure is a leading cause of morbidity and mortality, posing a major health and economic burden in the western world. Nearly 5 million Americans and 6.5 million Europeans suffer from heart failure, which accounts for 20% of all hospitalizations among patients over the age of 65, and its related complications result in one million admissions with an annual mortality rate of 8–10%. Moreover, heart failure has enormous economic impact because of the high costs of the treatment, frequent hospitalizations, and poor quality of life. Therefore, understanding the basic mechanisms leading to the development of heart failure and its complications, as well as the discovery of innovative adequate treatment for heart failure are crucial in order to improve the outcome of this devastating disease.

Humans present with heart failure of varying severity and of uncertain duration, produced by a wide variety of causes. This variability, and confounding effects of treatment, complicates the study of the pathophysiology and progression of the heart failure.

The ideal model should be able to reproduce each of the aspects of the progression of clinical heart failure. However, none of the models available is able to entirely reproduce heart failure. While some models reproduce neuroendocrine changes, others better reproduce the remodeling that occurs during chronic heart failure. Nevertheless, the progress that has been made so far and the expected future achievements in this field would not have been possible without the continuous development of experimental models of heart failure and hypertrophy in small and large animals, where each one has its unique advantages and limitations. There are three main surgical models of heart failure in rodents: coronary artery ligation to induce myocardial infarction; transverse aortic constriction to create a model of pressure overload; and aortocaval fistula to increase a model of volume overload.

RAT LEFT ANTERIOR DESCENDING (LAD) ARTERY LIGATION

The surgical method, first developed by Pfeffer and coworkers, consists of ligating the left coronary artery (Pfeffer 1979). In this procedure, left thoracotomy is performed on the anesthetized rat, and the heart is rapidly exteriorized by gentle pressure on the right side of the thorax. The left coronary artery is either ligated or heat cauterized between the pulmonary artery outflow tract and the left atrium. The heart is then returned to its normal position and the thorax immediately closed. Several modifications have been introduced to improve performance and to reduce animal mortality, and left coronary artery ligation is the most common method used to induce acute myocardial damage in rat and other animal models. If the left coronary artery is not completely ligated, heart failure may occur as a consequence of chronic myocardial ischemia. Complete occlusion of the left coronary artery results in myocardial infarction of variable sizes with occurrence of overt heart failure after 3–6 weeks in a subset of animals with large infarcts. The impairment of left ventricular function is related to the loss of myocardium. Failure is associated with left ventricular dilatation, reduced systolic function and increased filling pressures. The progression of left ventricular

dysfunction and myocardial failure is associated with neurohumoral activation similar to that seen in patients with chronic heart failure (CHF). In particular, it was shown that ACE (angiotensin-converting-enzyme) activity in the left ventricle correlated inversely with left ventricular function and that ACE activity in the kidney was only increased late after the induction of heart failure. Depressed myocardial function is associated with altered calcium transients. The density of L-type calcium channels, as evaluated by antagonist binding was shown to be decreased in moderate to severe stages of congestive heart failure. Furthermore, it was shown that after 4, 8 and 16 weeks following coronary artery ligation, SR (sarcoplasmic reticulum)-Ca²⁺-ATPase mRNA and protein levels decrease continuously with increasing severity of congestive heart failure. Interestingly, SR-Ca²⁺-ATPase activity was found to be more depressed than expected from the reduction in protein levels. Although a high initial mortality and induction of mild failure in most cases may be a disadvantage of this model, it seems to be very useful for long-term studies of pharmacological interventions on the neurohumoral activation.

One important modification is temporary occlusion followed by reperfusion, allowing flow recovery through the previously occluded coronary artery bed. Left coronary artery ligation can thus be used to evaluate diverse parameters resulting from either permanent ischemia or ischemia/reperfusion.

Preparation of the Operation

The operating surface is first prepared by disinfecting the area with 70% ethanol.

All surgical instruments are to be sterilized with a hot bead sterilizer before surgery (and in between individual rat surgeries). These instruments include: surgical scissors (2), forceps (1), curved forceps (1), needle holder (2), and a chest retractor.

Adjust the temperature of a homeothermic blanket system (heating pad), to be used to maintain the body temperature of the animal at 37±1°C, in order to prevent a dramatic fall in body temperature; the size of an infarct is dependent on the duration of occlusion as well as body temperature. Prior to the induction of anesthesia, animals will be examined to identify any pre-existing conditions that may complicate surgical outcome; physical examination will include visual inspection and measurement of heart rate, respiratory rate, and body temperature and body weight. Prior to anesthesia, each animal will receive a dosage of buprenorphine (0.1–2.5 mg/kg SQ).

Operative Steps

4. Rats are then anesthetized with 80 mg/kg of pentobarbital; the correct level of anesthesia is verified through the limb withdrawal response by applying pressure of the rat nail bed (toe-pinch reflex) and periodically throughout the procedure.
5. An electric shaver is then used to shave the fur from the neck and chest areas.
6. The shaved areas are to be scrubbed and disinfected with betadine solution followed by wiping the area with 70% alcohol; this betadine and alcohol scrub and disinfection procedure is to be repeated three times(Figure 1).|

Figure 1. Disinfection of surgical field.

7. The anesthetized animal is then placed in a supine position on a homeothermic blanket system (heating pad) in order to maintain body temperature.
8. Intubation is then performed by insertion of the endotracheal tube (polyethylene size 90; PE 90) where the tubing is beveled on the edge for ease of entrance through the larynx.

Figure 2. Open the thorax.

Figure 3. Pericardium is opened.

9. Mechanical ventilation is then achieved by connecting the endotracheal tube to Kent Scientific ventilator (TOPO Dual Mode) cycling at 80 breaths per minute and a tidal volume of 1.2 ml per 100 gram body weight.
10. Once steady breathing is established, the chest is opened at the left fourth intercostal space, by using hemostats or round end scissors to open the space, but without cutting the tissue so that the risk of bleeding can be reduced (Figure 2).

Figure 4. LAD is identified.

Figure 5. LAD is ligated using a 6-0 proline suture.

11. A chest retractor is then positioned within the fourth intercostal space in order to spread the ribs so that the left ventricle (LV) is exposed, taking maximal care not to damage the lung.
12. The pericardium is then opened, but left in place if possible (Figure 3).

Figure 6. Thorax cavity is closed.

Figure 7. Skin is closed using 6-0 proline suture.

13. The proximal left anterior descending (LAD) artery will be identified with the use of a surgical stereo microscope, and the LAD is then ligated using a 6-0 proline suture. Proper ligation of the LAD will be confirmed by observing blanching of myocardial tissue distal to the suture as well as dysfunction of the anterior wall; as observed during the transient LAD ligation (Figure 4 and Figure 5).
14. The chest retractor is then removed and the ribs are drawn together using a 2-0 proline suture with an interrupted suture pattern.
15. Once the ribs are closed, the outflow of the ventilator is again briefly (1–2 seconds) pinched off to ensure proper breathing (Figure 6).

The skin is closed using 6-0 proline suture with a continuous suture pattern (Figure 7).

Post-Operative Recovery

Once the surgery is complete, the body temperature (by a rectal thermometer), respiratory rate (by visual inspection), heart rate (by palpitation), and abnormal signs of pain are to be monitored until the animal becomes ambulatory. The rat will be removed from the ventilator and then be placed in an animal cage and allowed to recover from anesthesia.

RAT AORTIC BANDING

Placing a ligature around the ascending aorta induces pressure overload of the left ventricle, eventually resulting in left ventricular hypertrophy and failure. Aortic coarctation results in a very short reactive hyperreninemia of less than 4 days. Thereafter, the circulating

renin–angiotensin system is no longer activated, but the ventricular ACE activity begins to rise. After a period of several weeks, ventricular ACE activity may decrease again to normal values which may be related to normalization of wall stress with increasing hypertrophy. Numerous studies have been performed using aortic banding in rats to evaluate different aspects of left ventricular hypertrophy. Furthermore, after several months, a subset of animals goes into failure. In a recent study, chronic experimental aortic constriction imposed by banding of the ascending aorta in weanlings resulted in compensated left ventricular hypertrophy of the adult rats for several weeks. After 20 weeks of aortic banding, two distinct groups could be identified: rats without change in LV systolic pressure development and those with a significant reduction in left ventricular systolic pressure. The latter group exhibited increased left ventricular volumes, reduced ejection fraction and clinical signs of overt heart failure. Left ventricular hypertrophy and failure was associated with increased beta-myosin heavy chain mRNA and atrial natriuretic factor mRNA. Interestingly, a decrease in SR-Ca²⁺-ATPase mRNA levels by the polymerase chain reaction occurred in left ventricular myocardium from failing animals after 20 weeks of banding but not in nonfailing hypertrophied hearts. From this data, it was suggested that the decrease in SR-Ca²⁺-ATPase mRNA levels may be a marker of the transition from compensatory hypertrophy to failure in these animals. During compensated hypertrophy, while catecholamine levels are normal, there is activation of the local myocardial renin–angiotensin system, which may be important for the development of myocardial failure. With the development of heart failure, plasma catecholamine levels can increase.

This model seems to be well suited for studying the transition from hypertrophy to failure at the level of the myocardium. Nevertheless, one should keep in mind that considerable differences in the function of subcellular systems exist between rat and human myocardium.

Preparation of the Operation

Keep rat (approximately 200g body weight) under antibiotic umbrella 24 hr before surgery by administering amoxicillin orally (dose: 500 mg/L of water). Sterilize all surgical tools (such as scissors, forceps, clip applicator, suture needles, and needle holder) by autoclaving at 121°C for 15 min. Use a heating pad to maintain the animal body temperature around 37°C to avoid a rapid decrease in heart rate. Keep the rat on top of a temperature controlled heating pad in the supine position.

Remove fur from the neckline and left chest region of the rat (preferably using an electric shaver). Disinfect surgical site with povidone-iodine solution and then with 70% ethyl alcohol. Use a sterile drape to expose only the surgical site during the operative procedure. Note: As an additional option for the animal care, 0.25% Bupivacaine ID (2.5 mg/kg) can be incorporated prior to incising at each incision site for local anesthesia/analgesia.

Insert a 16 G I.V. Catheter into the rat's trachea through mouth. Connect the tracheal cannula to a rodent ventilator for maintaining a respiratory rate of 50 breaths/min, tidal volume of 1.70 ml and inspiration time of 0.60 sec (for rat with 200g body weight).

Operative Steps

1. After skin incision, the upper half of the sternum was divided in the midline using scissors.
2. The thymus was removed and aortic arch was carefully dissected free of the surrounding tissues (Figure 8 and Figure 9).

Figure 8. Upper half of the sternum was divided.

Figure 9. Thymus was removed and aortic arch exposed.

Figure 10. Suture is placed between the innominate and left carotid arteries.

3. Following identification of the transverse aorta, a small piece of a 5.0 silk suture is placed between the innominate and left carotid arteries (Figure 10).
4. Two loose knots are tied around the transverse aorta and a small piece of a 26½ gauge blunt needle is placed parallel to the transverse aorta. The first knot is quickly tied against the needle, followed by the second and the needle promptly removed in order to yield a constriction (Figure 11 and Figure 12).

Figure 11. Small piece of a 26½ gauge blunt needle is placed.

Figure 12. Needle removed.

Figure 13. Sternotomy closed.

5. The sternotomy and the skin incision were closed with 5-0 sutures (Figure 13).

Post-Operative Recovery

Remove tracheal cannula from the rat once spontaneous breathing is re-established.

Allow the animal to recover on the heating pad by gradually lowering the anesthesia and ventilator assisted respiration.

Postoperatively, the animals were kept in separate cages and allowed free access to water and standard laboratory diet. Analgesia with buprenorphine 0.05 mg/kg subcutaneously was provided every 12 hour for 48 hours.

MOUSE CORONARY LIGATION MODEL

One of the most widely used models of heart failure in mice is the left coronary artery ligation procedure, adapted from rat. In some protocols, the artery is occluded permanently, but recently procedures for temporary occlusion have been introduced to reproduce human ischemia/reperfusion injury (Michael 1995). In this method the left anterior descending coronary artery is occluded and then reperfused, allowing flow recovery through the previously occluded coronary artery bed. Reperfusion is monitored visually, and the infarct can be analyzed by histopathological techniques, and can be documented in real time by noninvasive high frequency. The areas at risk and the infarct size are revealed by staining with Evans blue dye and triphenyltetrazolium chloride and are assessed by computerized planimetry. This model has confirmed the benefits of reperfusion, since infarct size was found to be significantly lower than after permanent occlusion of the coronary artery. The method has been further modified to analyze ischemic preconditioning of the heart. In this method, the left coronary artery is repeatedly occluded to subject the heart to several rounds of brief ischemia and reperfusion followed by permanent occlusion. This approach has identified several ischemia-induced genes that confer tolerance to a subsequent ischemic event (West 2008).

Figure 14. Intubated mouse on surgical area.

Preparation of the Operation

Before proceeding to surgery, anesthetize mouse that is 6 weeks of age or older by inhalation of 2–5% isoflurane. Perform a toe pinch to confirm that the animal is sufficiently anesthetized.

The unconscious mouse is placed on its back on a warm pad to maintain a constant temperature of 37°C. The precordial chest on the left side is shaved.

Secure the mouse to an intubation device with an isoflurane-filled chamber. Insert a tube of 0.2 inner diameter into the mouse's trachea through mouth, then place the intubated mouse on an aseptic surgical area (37°C by a temperature controller) and connect the endotracheal tube to a ventilator (rate of 120 per min, pressure of 4–6 mmH₂O) (Figure 14); disinfect the area with betadine and 75% ethanol.

Apply ophthalmic ointment to the mouse's eyes.

Operative Steps

6. Use sterile scissors to make a 1.5 cm incision along the mid-axillary line. Scissors are used rather than a scalpel to avoid injury to the underlying tissue in mice (Figure 15). Then, use blunt-tip vessel scissors to dissect and retract the precordial muscle from the chest wall.
7. Perform a left thoracotomy between the third and fourth ribs to visualize the anterior surface of the heart and left lung.
8. Further retract the thoracic wall using a suitable retractor in order to improve visualization and accessibility. Remove the pericardium by using toothed forceps and blunt-tipped scissors (Figure 16).

Figure 15. Section of skin.

Figure 16. Left thoracotomy.

9. Ligate the left coronary artery by placing the needle (attached with 7-0 suture) beneath the artery with a band of myocardium between the ligature and the artery (Figure 17). A successful occlusion of coronary artery is verified by hypokinesia/akinesia of the anterior left ventricular wall and by the alterations of ECG recording (*e.g.* ST segment elevation, QRS broadening)
10. Close the chest by placing two stitches (6-0 suture) on the third and fourth ribs.

Figure 17. Ligate the left coronary artery.

Figure 18. Close chest.

Use 5-0 suture to close the skin (Figure 18).

Post-Operative Recovery

For post-operative analgesia, administer a single intraperitoneal injection of buprenorphine (0.05 mg/kg). The animals will spontaneously recover within 2–5 min after stopping isoflurane anesthesia. Finally, place the mouse in a warm cage and provide 0.6 mg/ml of buprenorphine in the drinking water to prevent post-operative distress. Closely monitor the mouse for the first 24 hours after surgery.

Echocardiography is performed to evaluate cardiac function 3 days after myocardial infarction.

MOUSE AORTIC BANDING

The technique for transverse aortic constriction has also been adapted for use in mice (Rockman 1991). After anesthetic and thoracotomy of an adult mouse (an 8-week-old mouse is most commonly used), a 27-gauge needle is placed alongside the transverse aorta between the innominate and left carotid arteries. A nylon suture is tied around the vessel and needle, which is then withdrawn, leaving a 0.4-mm-diameter aperture. By this method, a stable, relatively reproducible 35–45 mm Hg gradient can be introduced across the experimental constriction. The intraoperative mortality reported in the original paper was around 10%, which remains the approximate value in current studies. Crucially, Rockman et al. have been able to show that the molecular pathways activated in their postoperative mouse hearts were identical to other animal and cellular models of cardiac hypertrophy (Rockman 1994). The

disadvantages of this approach are that, in absolute terms, intraoperative mortality is high, and as aortic banding is more technically demanding in the mouse than the rat, results are operator-dependent, with heart failure developing within weeks of the procedure in the surviving mice. However, the cost savings by using mice, and the huge range of genetic reagents available, may mitigate these disadvantages. It is not clear how applicable this system is to cardiac hypertrophy/failure due to aortic stenosis in humans, but it has allowed several advances in understanding the molecular control mechanisms underlying left ventricular hypertrophy.

Preparation of the Operation

The operating field is disinfected with 75% isopropyl alcohol. Make sure the heating pad is on and at the right temperature. A recommended system is a circulating water pump connected to a therapy pad that is maintained at $37^{\circ}\text{C} \pm 1^{\circ}\text{C}$. It is important to maintain normal body temperature during surgery as to avoid a rapid decrease in heart rate. Surgical tools are sterilized in a hot bead sterilizer before surgery. For this procedure, you will need the following surgical instruments: blunt scissors, course curved forceps $\times 2$, fine 45° angled forceps $\times 2$, angled spring scissors, chest retractor, and needle holder.

Cotton applicators should be on hand in case of bleeding.

Mice are anesthetized in an induction chamber with 2% isoflurane mixed with 0.5–1.0 L/min 100% O_2 . Hair clippers are used to shave the fur from the neckline to mid chest level. The mouse is placed in a supine position atop a heating pad in order to maintain body temperature. A rubber band is placed over the animal's front teeth to extend the neck. Using curved forceps in one hand, the tongue is gently manipulated to the side. With the other hand, endotracheal intubation is performed using PE 90 tubing. The endotracheal tube is then connected to a Harvard volume-cycled rodent ventilator cycling at 125–150 breaths/minute and a tidal volume of 0.1–0.3 ml. During the surgical procedure, anesthesia is maintained at 1.5–2% isoflurane with 0.5–1.0 L/min 100% O_2 . Correct level of anesthesia is verified by applying pressure on the mouse nail bed (toe-pinch reflex).

The surgical field is disinfected with betadine solution followed by 70% alcohol. This procedure is repeated three times.

To prevent contamination of the surgical field during the operation, a sterile drape is placed over the mouse leaving only the operation field exposed.

A set of sterile gloves is used for each individual mouse.

Operative Steps

11. Partial thoracotomy to the second rib is performed under a surgical microscope and the sternum retracted using a chest retractor (Figure 19).
12. Fine tip 45° angled forceps are used to gently separate the thymus and fat tissue from the aortic arch.

Figure 19. Partial thoracotomy.

13. Following identification of the transverse aorta, a small piece of a 6.0 silk suture is placed between the innominate and left carotid arteries (Figure 20; 21).

Figure 20. Identification of the transverse aorta.

Figure 21. Suture is placed between the innominate and left carotid arteries.

14. Two loose knots are tied around the transverse aorta and a small piece of a 27½ gauge blunt needle is placed parallel to the transverse aorta (Figure 22). The first knot is quickly tied against the needle, followed by the second (Figure 23) and the needle promptly removed in order to yield a constriction of 0.4 mm in diameter (Figure 24).

Figure 22. Small piece blunt needle is placed parallel to the transverse aorta.

Figure 23. The second knot.

15. The chest retractor is removed and the outflow of the ventilator pinched off for 2 seconds to re-inflate the lungs (Figure 25).

Figure 24. Needle removed and yield a constriction of 0.4 mm in diameter.

17. The skin is closed using a 6.0 proline suture with a continuous suture pattern (Figure 27).

Figure 26. Chest cage is closed.

Figure 27. Skin is closed using a 6.0 proline suture.

Post-Operative Recovery

For post-operative analgesia, the mouse is injected with buprenorphine (0.1 mg/kg) intraperitoneally. If there are signs of dehydration after surgery, sterile saline is given intraperitoneally.

Anesthesia is gradually lowered to the off position and the endotracheal tube removed when signs of spontaneous breathing occur.

The mouse is moved to the prone position and allowed to recover on a heating pad.

AORTO-CAVAL FISTULA (ACF)

The rat aortocaval fistula (ACF) model is considered to be a model of high-output heart failure, its long-term renal and cardiac manifestations are similar to those seen in patients with low-output heart failure. These include Na^+ -retention, cardiac hypertrophy and increased activity of both vasoconstrictor/antinatriuretic neuro hormonal systems and compensatory vasodilating/natriuretic systems. Progression of cardiorenal pathophysiology in this model is largely determined by balance between opposing hormonal forces, as reflected in states of heart failure decompensation that are characterized by overactivation of vasoconstrictive/ Na^+ -retaining systems.

Since this model mimics high cardiac output clinical heart failure, it may be suitable to study myocardial alterations, mainly cardiac hypertrophy characterizing these patients.

Thus, ACF serves as a simple, cheap, and reproducible platform to investigate the pathogenesis of heart failure and to examine efficacy of new therapeutic approaches (Liu 1991).

Preparation of the Operation

Male Sprague-Dawley rats weighing 250 to 300 g were anesthetized with pentobarbital sodium (40 mg/kg of body weight). Use a heating pad to maintain the animal body temperature around 37°C to avoid a rapid decrease in heart rate. Take care to avoid dehydration of the animal before and during surgery. Check the pedal reflex to confirm successful anesthesia.

Operative Steps

18. Dissecting the vena cava and the aorta from the surrounding tissues, but not from each other (Figure 28).
19. Miniature vessels clamp was placed approximately 10 mm distal to the origin of the renal arteries (Figure 29).
20. 1.5 mm opening was cut into the lateral wall of the vena cava and the aorta.
21. Vena cava to aorta side-to-side anastomosis was made by continuous 0.6 size proline suture (Figure 30).
22. After the vessel clamps were released, arterial blood could be seen vigorously entering the vena cava through the fistula and mixing with the darker venous blood (Figure 31).
23. Time of occlusion of both vessels did not exceed 10 minutes.

Figure 28. Dissecting the vena cava and the aorta.

Figure 29. Clamp was placed on vena cava and aorta.

Figure 30. Vena cava to aorta side-to-side anastomosis.

Figure 31. Vessel clamps are released.

POST-OPERATIVE RECOVERY

For post-operative analgesia, administer a single intraperitoneal injection of buprenorphine (0.05 mg/kg). Place the rat in a warm cage and closely monitor the rat for the first 24 hours after surgery.

CONCLUSION

The use of animal models has proven to be an extremely valuable tool in understanding the pathophysiology of complex cardiovascular disease mimicking congestive HF. The ideal animal model of cardiovascular disease will mimic the human subject metabolically and pathophysiologically, will be large enough to permit physiological and metabolic studies, and will develop end-stage disease comparable to those in humans. Given the complex multifactorial nature of CVD, no species or animal model will be similar to the human disease and thus the models should be chosen according to the study aim. Animal models may also be relevant to study the effects of new pharmacological interventions on hemodynamics, neurohumoral activation and survival under preclinical conditions. At present, transgenic models of congestive HF are essential for understanding the molecular alterations underlying the development of the disease, as they allow the identification of genes that are causative for HF and to characterize molecular mechanisms responsible for the development and progression of the disease. Animal models which mimic distinct features of human HF will play an important role in unravelling the consequences of gene transfer and molecular techniques to correct disturbed subcellular processes in the failing heart. These experiments

are indispensable and these rodent models will continue to hold an important role, not only in expanding our knowledge about the mechanisms underlying HF, but also in developing novel therapeutic strategies for this syndrome.

HEPATOPANCREATOBILIARY SURGERY EXPERIMENTAL MODELS

***Paulo N. Martins*, MD, PhD, Natalie Bath, MD
and Adel Bozorgzadeh, MD***

Department of Surgery, Division of Organ Transplantation,
UMass Memorial Medical Center, University Campus, Worcester, MA, US

ABSTRACT

Well-characterized animal models of human diseases are fundamental for the analysis of pathophysiologic mechanisms and the development of new treatment strategies. A better understanding of the underlying pathophysiology of hepatopancreatobiliary (HPB) disease may lead to more targeted therapeutic options, potentially leading to improved survival. We will focus this chapter on rodent HPB models. Owing to the low cost of experiments, easily handling, and availability of a variety of genetically modified strains, rodents have become a popular model organism for such experiments.

Despite some limitations, the use of rodent models in HPB surgery provides essential investigative tools to study many important phenomena in HPB research. Due to the availability of large varieties of genetically modified species and monoclonal antibodies, more relevant and more specific questions can be answered utilizing rodent models. Most of these procedures only require basic surgical skills, and they have been performed with high reproducibility, which has been tolerated very well with minimal operative mortality. However, some procedures require microsurgical skills to be performed accurately and reproducibly. Increased knowledge of the rat and mouse liver surgical anatomy and more advanced microsurgical skills permit individualized dissection, and individual ligation of vascular and biliary branches.

Here we will review the HPB anatomy; techniques for hepatectomy, bile duct ligation, and portal systemic shunts; models of cirrhosis; models of acute liver failure; models of hepatocellular carcinoma (HCC) and cholangiocarcinoma (CCC); model of hepatic metastases of colon carcinoma; pancreatitis; and common bile duct (CBD) stricture.

TAA	Thioacetamide

LIVER ANATOMY

Introduction

The rat is the most used experimental model in hepatopancreatobiliary (HPB) surgical research because of many factors, in particular because it is easy to handle and inexpensive (Rodriguez 1999; Martins 2003). In hepatic regeneration, liver metastasis, transplantation immunology and hepatic disease studies, the rat is by far the most frequently used model. On the other hand, the majority of studies that led to advances in techniques of liver resection and transplantation have used the porcine and canine model. Virtually all procedures in liver surgery can be performed in the rat including segmental liver resections, porto-systemic

shunts, transplantation of full and partial organs, and vascular embolizations. As a result of the great anatomical variability of liver anatomy such as its extrahepatic biliary tract and vascularization, the knowledge of anatomy is advantageous because it permits individualized dissection, parenchymal section, ligature of specific vascular and biliary branches, and avoids damage of other structures.

The objective of this study was to systematically describe and illustrate the surgical anatomy of the rat liver to facilitate the planning and performance of HPB surgery studies in this animal.

Liver Anatomy

The rat and mouse livers are multi-lobulated as in other mammals (Lorente 1995; Flower 1872; Martins 2007). In rats, the liver mass represents approximately 5% of the total body weight compared to 2.5% in adult humans.

Surfaces

With the rat placed in decubitus position, the rat liver has three surfaces: superior, inferior and posterior. A sharp, well-defined margin divides the inferior from the superior surface. Unique from the human liver, the other margins of the liver are also sharp. Although the rat liver is lobulated, it has rather uniform surfaces since the lobes lie flat against each other as seen in Figure 1A. The only exception to this is the posterior caudate lobe, which is separated from the remainder liver by the stomach.

The *superior (parietal) surface*, convex as a whole, comprises a part of the left lateral and medial lobes and fits under the vault of the diaphragm. It is completely covered by peritoneum except along the line of attachment of the falciform ligament. The line of attachment of the falciform ligament divides the liver into two parts, termed the right and left lobes. In comparison to the human liver in which the right lobe is much larger than the left, the rat left and right liver have approximately the same volume.

The *inferior (visceral) surface* is uneven, concave, and it is in close proximity to the stomach, duodenum, right colic flexure, the superior part of the pancreas, the right kidney and suprarenal gland. The rat liver inferior surface does not have the fossae in the shape of the letter “H” as in humans. This surface is almost completely invested by peritoneum. Through the porta (transverse fissure) travels the portal vein, the hepatic artery and nerves, the hepatic duct and lymphatics. Liver impressions (colic, renal, duodenal, and suprarenal) are not as evident as in human livers.

The *posterior surface* it is not covered by peritoneum over some part of its extent, and it is in direct contact with the diaphragm. It extends obliquely between the caudate lobe and the bare area of the liver. The inferior vena cava is completely intrahepatic.

Abbreviations: AC: anterior caudate lobe, CBD common bile duct, Panc pancreas, CT celiac trunk, PHA proper hepatic artery, SA splenic artery, A aorta, LGA left gastric artery, Ly lymph node, S stomach, D duodenum, RK right kidney, SHVC supra-hepatic vena cava, GB gallbladder, FL falciform ligament, P portal vein, IVC inferior vena cava, RLL right lower lobe, ML middle lobe, RML right middle lobe, LML left middle lobe, CL caudate lobe, LLL left lateral lobe, RL right lobe.

Figure 1. Rat liver “in-situ”. (A) Anterior view, (B) Anterior view after separating the lobes, (C) Porta hepatis, (D) Portal vein and common bile duct descending in the pancreatic tissue along the duodenum (the point of insertion of the CBD in the duodenum is marked with a X), (E) Celiac trunk and its branches: proper hepatic, left gastric and splenic arteries. (F) Magnification of the portal triad: portal vein, CBD, proper hepatic artery and a hilar lymph node.

Ligaments

Similar to the human liver, the rat liver is connected to the under surface of the diaphragm and to the anterior wall of the abdomen by five ligaments: the *falciform*, the *coronary*, two *lateral* which are peritoneal folds, and the *round ligament* – a fibrous cord which represents the obliterated umbilical vein. The liver is also attached to the lesser curvature of the stomach by the hepatogastric ligament and to the duodenum by the hepatoduodenal ligament.

Liver Lobes

The rat's liver lobes, like the human liver, are named after the portal branches that supply them due to the fact that the portal system is the most constant anatomical reference among mammals (Flower 1872; Lorente 1995; Martins 2007) (See Figures 1–6).

The *middle* or *median lobe* is the largest lobe, accounting for approximately 38% of the liver weight. It is fixed between the diaphragm and abdominal wall by the falciform ligament.

It is in continuity with the left lateral lobe and is subdivided by a vertical fissure (main fissure or umbilical fissure) into a large right medial lobe (2/3 of the volume of the medial lobe) and a smaller left medial lobe (1/3 of the volume). The right medial lobe has both left and right hepatic vascular components. (Lorente 1995; Kogure 1999; Martins 2007).

Abbreviations: GB: gallbladder, FL: falciform ligament.

Figure 2. A, B. Anterior view of the mouse liver showing the location of the gallbladder and falciform ligament. B) Visceral view of the mouse liver.

Abbreviations: the same as in Figure 1 and 2.

Figure 3. Rat liver “ex-situ”. (A) Anterior view, (B) Inferior (visceral) view (C) Anterior after separating the lobes, (D) posterior view, (E) Superior view with the lobes in normal position, (F) Superior view with lobes flattened and separated from each other (note here a millimetric scale on the bottom). When the liver is ex-situ, the anterior and posterior caudate lobes are on the same plane (see in E), and the anterior lobe lies superiorly. Note in D that the inferior vena cava is completely intrahepatic (a plastic catheter is inside the inferior vena cava).

The *right lobe*, located to the right of the vena cava and posteriorly in the right hypochondrium, is almost completely covered by the medial lobe. It comprises approximately 22% of the liver weight and is divided by a horizontal fissure into two pyramidal-shaped lobules, the superior (SRL, superior right lobe, also called right posterior lobe) and inferior (IRL, inferior right lobe, also called right anterior lobe) lobules.

The *left lateral lobe* is flattened and situated in the epigastric and left hypochondriac regions over the anterior aspect of the stomach. Its medial portion is covered by the left part of the medial lobe. Its upper surface is slightly convex and is molded on the diaphragm. It has no fissures.

The *caudate lobe* is situated behind the left lateral lobe and to the left of the vena porta and inferior cava vein. It comprises 8 to 10% of the liver weight and is divided into two portions: the *paracaval portion (caudate process)* - which accounts for 2 to 3% of the liver mass, encircles the inferior vena cava and bridges the caudate lobes and the right lateral lobe; and the *Spiegel lobe*, which has an *anterior* (superior) and a *posterior* (inferior) portion in form of discs, each representing 4% of the liver mass. The anterior part of the caudate lobe is located anterior to the esophagus and stomach and its pedicle lies superior, while the posterior is located behind these structures and its pedicle lies inferior (Figure 3). Both are covered by a very thin layer of peritoneum, the hepatoduodenal and hepatogastric ligaments.

Liver Vasculature

The origin and course of the major vessels are similar to those of humans; no variability in vessel origin was identified in this small number of animals. However, there have been many variations of the liver vasculature described (Flower 1872; Greene 1963; Castaing 1980; Brand 1995; Lorente 1995; Wu 2005; Martins 2007). The most common anatomy of liver vasculature and biliary system is shown on Figure 4.

Abbreviations: the same as in Figure 2.

Figure 4. Most common anatomy of the hepatic veins (A), portal vein (B) and biliary system (C) of the rat.

Hepatic Artery

The liver is supplied by the hepatic artery proper, which originates from the common hepatic artery. The celiac trunk, which is relatively longer in rats than in humans, originates at the anterior or right aspect of the abdominal aorta just below the diaphragm pillars, ascends closely to the aorta for 5 to 7 mm and branches into the common hepatic, left gastric and splenic arteries (Brand 1995) (Figure 1E). The common hepatic artery runs within the pancreas and bifurcates at the level of the portal vein into hepatic artery proper and gastroduodenal artery. The hepatic proper artery has a diameter between 0.2 to 0.5 mm and length between 4 to 5 mm. The hepatic artery proper runs at the posterior surface of the portal vein, and at the liver hilum it divides into the right and left branches (Figure 1F). The arterial branches run on the anterior surface of the portal vein, pass behind the major hepatic ducts and follow a parallel course with the portal vein branches as they divide into their main lobar ramifications. Sometimes two lobar arteries accompany one single lobar portal vein. The most visible branches are for the superior right lateral, inferior right lateral and medial lobes. In addition to the four branches to the main hepatic lobes, the hepatic artery proper gives off a branch, which can be difficult to visualize, called hepato-esophageal artery. This branch arises on the hepatic pedicle between the caudate and left lobes measuring 10 to 12 mm in length and 0.1 mm in diameter and supplies the lower two-thirds of the esophagus (Leneman 1967). It was not found in the literature description of the intrahepatic arterial branches.

Portal Vein

The extrahepatic portal vein is located posterior and lateral to the hepatic artery and common bile duct (Figure 1C–D). It is formed from the superior mesenteric vein, the gastrosplenic vein, and the gastroduodenal vein Innocenti P (1978). The pancreaticoduodenal vein and inferior mesenteric vein drain into the superior mesenteric vein. In this series, the range of diameter and length of the portal vein was 2 to 4 mm and 4 to 7 mm, respectively.

The rat liver has three main portal branches, which determine the following fissures: left portal fissure, right portal fissure and main portal fissure. The left portal fissure separates the right lower lobe (RLL) from the middle lobe (ML), the main fissure separates the right middle lobe (RML) from the left middle lobe (LML), and the left fissure (corresponding to the fossa for the ductus venosus in the human liver), which separates the caudate lobe (CL) from the left lateral lobe (LLL). At the porta hepatis the common portal vein gives branches first to the right lobe (RL), then to the CL, then to ML and last to the LLL (Lorente 1995; Martins 2007). The left, right, and caudate lobes have one primary portal branch, whereas the middle lobe has two portal branches. The right portal vein immediately divides into two branches, one for the superior right lobule and inferior right lobule. The portal branch to the caudate lobe is very short, branching into two main veins, one for anterior and one for the posterior Spiegel lobe. Other very small veins, originating directly from the main portal vein and its left and right branches, supply the paracaval portion (caudate process).

Hepatic Veins

The inferior right lobe and the superior right lobe drain into the inferior vena cava in most cases by one branch each, but each of them can be drained by two veins. In humans, they correspond to the right hepatic and inferior right hepatic vein, the latter representing a variation of the normal anatomy. The middle lobe has two or three large hepatic veins (right, middle and left median veins) (Lorente 1995; Kogure 1999; Martins 2007). The right and left portions of the middle lobe are drained each by one vein. As in humans, the vein draining the left portion of the middle lobe (left medial vein) may enter the vena cava separately or may join the vein draining left lateral lobe (left hepatic vein) to form a common trunk before joining the suprahepatic cava vein (Gershbein 1954; Lorente 1995). The left and caudate lobes are drained in most cases by two large hepatic veins (left and right) that open separately into the vena cava, but in some cases they can be united by a common trunk. The caudate process drains into the intrahepatic vena cava through multiple branches (Figure 4).

Biliary Tract

While the mouse has a gallbladder, the rat does not. The extrahepatic biliary ducts of the rat are formed by first order branches of each liver lobe. Second order branches exist for the superior and inferior caudate lobes, right middle lobe and caudate process. The rat biliary tract has many anatomical variations.

Most commonly each lobe is drained by its own bile ducts. The left lateral lobe is most frequently (in 62.5% of cases) drained by two biliary branches. The middle lobe is drained by branches from the right middle lobe (1 to 4 branches) and left medial lobe. In 57.5% of cases each caudate lobe has one branch that join together to form a common branch before draining into the common bile duct (CBD) (Lorente 1995). The superior part of the caudate process drains into branches of the right lateral lobe or the main biliary trunk, while the inferior part of it drains into the branches of the caudate process or to the branch of the right lateral lobe. (Figure 4) (Lorente 1995; Martins 2007).

The common bile duct is formed by the junction of the main hepatic ducts. The main hepatic ducts join together on the caudate process (Figure 1C). In this series, the CBD ranged from 12 to 16 mm of length and from 0.6 to 1 mm of diameter, but it can be up to 45 mm long (Mann 1920; Hebel 1976; Lorente 1995). The CBD descends to the left of the hepatic artery and the portal vein on the surface of the caudate process and portal vein, then along the right border of the lesser omentum, keeping some distance from them (Figure 1D). A long extent of the CBD is completely imbedded in the pancreas, which has a diffuse and lobulated appearance. The CBD opens at the medial side of the descending portion of the duodenum, a little below its middle and about 10 to 22 mm from the pylorus (Figure 1C, D and F). The extrahepatic biliary system of the rat has also small intercommunicating branches.

Correlation between Rodent and Human Liver Anatomy and Limitations

The anatomical relationship between the human and rat liver is still undefined (Kogure 1999; Kano 2000). The phylogenetic distance between primates and rodents is more than 80 million years. The functional anatomy of the liver in the rat has been considered different

from humans but similar to the pig (Lorente 1995). The classical description of the human liver segmentation by Couinaud divided the human liver into eight segments, and this constitutes the basis of hepatic resections (Figure 6B). Three hepatic veins divide the liver into four sectors (right lateral sector, right paramedian sector, left paramedian sector, and left lateral sector) and each sector receives a portal pedicle, which bifurcates and supplies each lobe (I-VIII). Later, Couinaud classified the paracaval portion of the caudate lobe as an independent segment (IX) (Bismuth 1982; Couinaud 1994; Kogure 1999).

The nomenclature of the rat liver lobes is not uniform (Gershbein 1954; Nettelblad 1954; Lorente 1995; Kogure 1999). Most authors consider the rat liver to be divided into four lobes: *left lateral lobe*, *medial lobe* (left medial and right medial), *caudate lobe* (anterior or inferior, and posterior or superior), and *right lobe*. Lorente et al. divided the rat liver into two parts, superior liver and inferior liver, and six sectors: sector 1 or caudate process (CP), sector 2 or caudate lobe (CL), sector 3 or right liver lobe (RLL), sector 4 or right portion of right medial lobe (RML), sector 5 central and left part of the right medial lobe (RML) plus the left medial lobe (LML), and sector 6 made up by the left lateral lobe (LLL) (Figure 1–6) (Lorente L 1995). In a recent study from Kongure et al., comparing the rat and human liver, it was shown that the hepatic lobes of the rat are equivalent to the human liver. The rat caudate lobe (Spiegel lobe and paracaval portion) corresponds to segments I and IX, the rat left lobe corresponds to segment II, the rat middle lobe corresponds to segments III, IV, V, and VIII, and the right lobe to segments VI and VII (Kogure 1999). The human caudate lobe, although seems to be only one structure, is functionally divided into three parts (Couinaud 1994). In the rat, the three functional subdivisions of the caudate lobe are individualized structures.

In the rat, the mass of each lobe is relatively constant. Thus, the two anterior lobes, the two right liver lobes, and the two omental lobes (forming the caudate lobe) comprise approximately 70%, 22%, 8% of the liver, respectively (Figure 6A). Additionally, each lobe has its own pedicle containing a portal triad. These unique aspects of rat liver anatomy make resections of various extents simple and highly reproducible when performing experiments (Rodriguez 1999). In the rat, the left hemi-liver consists of the LLL, CL and LML while the right hemi-liver represents RL (SRL+IRL) and the RML. In comparison to the human liver in which the right hemi-liver has a greater volume than the left, the left and right hemi-livers in rats have similar volumes (Figure 6).

Figure 5. (A, B) Liver hilum.

Abbreviations: CP caudate process, AC anterior caudate lobe, PC posterior caudate lobe, SRL superior right lateral lobe, IRL inferior right lateral lobe, ML median lobe, RML right portion of the medial lobe, LML left portion of the medial lobe, LLL left lateral lobe, MF median fissure, LF left fissure, RF right fissure and FL falciform ligament, PV portal vein, IVC inferior vena cava.

Figure 6. A) Visceral surface of the rat liver showing lobes and their mean relative weight. The liver mass of which lobe in the rat is quite constant. The caudate lobe is formed by the CP, AC and PC, the right liver lobe is formed by SRL and IRL, and the medial lobe formed by LM and RM. B) Visceral surface of a human liver showing division into segments according to Couinaud's nomenclature. The segment VIII is superior to the segment V and cannot be seen in this figure. According to Kongure K, in the rat, CL, LLL, LML, RML, (IRL+SRL) represent in humans segments I and IX, the segment II, segments III, IV, V, and VIII; and the segments VI and VII, respectively. In the rat, the left hemi-liver consists of the LLL, CL and LML while the right hemi-liver represents RL (SRL+IRL) and the RML.

Differently from humans, dogs, pigs and mice, rats do not have gallbladders. However, other mammals, like the horse and deer, do not have it either. The functional implications of that are not known (Mann 1920). Small intrahepatic bile ducts in rats are thought to correspond to bile ductules in humans and large bile ducts in rats may correspond to human interlobular bile ducts (Alpini 1996). The extrahepatic biliary ducts of the rat are more superficial and the CBD is proportionally longer compared to the human liver. Second order branches exist for the superior and inferior caudate lobes, right middle lobe and caudate process. There are many anatomical variations. For a thorough description of the rat biliary system, see Lorente (Lorente 1995). The extrahepatic biliary system of the rat has also intercommunicating branches that implies existence of a biliary network (Lorente 1995). This also implies that it may be difficult to produce cholestasis selectively in one of the hepatic lobes. The branches of the left middle lobe generally drain into branches of the left lateral lobe, implying the existence of a biliary functional inter-relationship between the left middle lobe and the left lateral lobe. The resection of the left lateral lobe can result in extrahepatic cholestasis of the left middle lobe in some animals. Thus, caution is necessary when trying to translate conclusions from hepatic resection models to humans (Lorente 1995; Lorente 1995; Martins 2007).

Unique from the human CBD, which has a short intra-pancreatic course and lies to the right of the portal vein and in close proximity to it and the hepatic artery, the rat CBD has a long trajectory inside the pancreas and to the left of the hepatic artery and the portal vein, which results in some distance between it and the hepatic artery and portal vein (Figure 1D). The CBD can be easily cannulated for experiments to measure bile flow, liver function or for

anastomosis using a splint in liver transplantation. Most studies that cannulated the common bile duct used a polyethylene tubing (PE-10, inner diameter of 0.28 mm, outer diameter of 0.61 mm). However, a 24 gauge catheter can also be inserted into the CBD.

The origin and course of the major extrahepatic vessels are similar to humans. However, the branching pattern of the rat portal vein is different from humans. In the rat, the portal vein trifurcates, while in humans it bifurcates (Kogure 1999). Due to the fact that the rat liver is lobulated, there is no interdigitation between portal and venous pedicles; however, each one of the six sectors receives a portal pedicle and has its own venous pedicle (Lorente 1995). However, at microscopic level interdigitations may occur (Gershbein 1954). The inferior vena cava, differently from humans, is completely intrahepatic. The hepato-esophageal artery provides the liver with supra and infra-diaphragmatic systems of collateral circulation, once its ascending branches anastomose with branches of the mediastinal arteries and its descending branches communicate with the cardiac branches of the gastric artery. Thus, in experiments designed to provide arterial supply deprivation to the liver, the hepato-esophageal artery as a collateral route should be considered and previously ligated (Delong 1953).

Pancreas Anatomy

Rats are commonly used as experimental models for partial and total pancreatectomy. It is important to note that the biliary system in rats has numerous anatomical variations. After introducing latex dye into the biliopancreatic duct, portal vein and arteries, pancreas anatomy present in rats was further delineated as seen in a study by ME Kara, et al. (Kara 2005). The pancreas was subsequently divided into three parts following latex injection: biliary, duodenal, and gastrosplenic. The biliopancreatic and pancreatic ducts, biliary, and duodenal portions of the pancreas can be visualized with relative ease by retracting the duodenum caudally. The gastrosplenic portion of the pancreas was seen between the descending duodenum and transverse colon on the right side just caudal to the liver. In order to visualize the pancreas in its entirety, it was necessary to remove the stomach and duodenum. This maneuver also permitted visualization of the pancreaticoduodenal, right gastroepiploic and splenic vessels, and portal vein.

In the study by Kara, et al., the biliopancreatic duct diameter and length of ducts was found to be 1.01 ± 0.03 and 28.86 ± 0.59 mm, respectively. The anterior pancreatic duct originated from the biliopancreatic duct on different sides and was found to drain the entire gastrosplenic portion and part of the duodenal portion of the pancreas. The posterior pancreatic duct opened into the biliopancreatic duct and was found to do this at the level of the papilla in more than 1/3 of specimens, which is an important consideration when ligating the biliopancreatic duct at the level of the duodenal opening. The posterior pancreatic duct also carries the exocrine secretion from the duodenal portion of the pancreas to the biliopancreatic duct. Numerous minor ducts were also noted that drained all three portions of the pancreas directly into the biliopancreatic duct (Kara 2005). A thorough understanding of the anatomy found in the rat pancreas is imperative when using this model to study pancreatic transplantation and regeneration, treatment of pancreatitis, and metabolic or endocrine studies (Figures 5–11).

HEPATECTOMY MODELS

Introduction

Hepatic resections in rodents are performed to study liver regeneration, acute liver failure, tumor dormancy of hepatic metastasis, hepatic function, and response to stress and trauma (Higgins 1931; Bucher 1964; Weinbren 1965; Aleksandrowicz 1981; Rozga 1986; Lin 1990; Panis 1990; de Jong 1995; de Jong 1998; Lu 1999; Fausto 2005). Each lobe has its own pedicle containing a portal triad, and as a result hepatic resections of various extents in rodents are simple and highly reproducible. Hepatectomies both in the rat and mouse require basic surgical skills and have been performed with high success rates (Higgins 1931; Weinbren 1965; Pinto 1987; Lorente 1995; Rodriguez 1999; Fausto 2005; Madrahimov 2006; Martins 2007). In this review, we outline various models, different techniques and limitations of hepatic resections.

Models of Liver Resection

The classic rat model of partial hepatectomy in rats is based on the seminal experiments by Higgins and Anderson from 1931 (Higgins 1931). These investigations demonstrated that resection of the two anterior lobes (median and left lateral lobes) is easy to perform and creates a highly standardized liver reduction of approximately 70%. The classical 70% hepatectomy model in rats is the most popular because it has been extensively studied and can be accomplished in an expedited fashion with a single ligature of the common pedicle (Higgins 1931; Rodriguez 1999). It is also commonly employed in auxiliary liver transplantation models (Wang 2002).

In other models, 90%, 95% and 97% liver tissue resections are employed to study liver regeneration and acute liver failure (Gaub 1984; Emond 1989; Madrahimov 2006). In the 90% hepatectomy the right lobes, median lobe, and the left lateral lobe are resected. In the 95% hepatectomy model, the anterior caudate lobe is also removed, while in the 97% hepatectomy the anterior and posterior caudate lobes are removed, and only the paracaval portion remains. Other extents of resection can also be performed, however with more technical difficulty and higher complication rates (Figure 12).

In the mouse the relative volume of the lobes slightly differs from the rat. The right superior lobe represents $16.6 \pm 1.4\%$, the right inferior $14.7 \pm 1.4\%$, the median lobe $26.2 \pm 1.9\%$, and the left lateral lobe represents $34.4 \pm 1.9\%$ (Inderbitzin 2004), while in the rat it represents approximately 22%, 10%, 38%, 30%, respectively (Lorente 1995; Madrahimov 2006; Martins 2007). On the other hand, in humans, the average volume ratios of the left lateral segments (II and III), left medial segment (IV), caudate lobe (I and IX), right anterior segments (V and VIII), and right posterior segments (VI and VII) are 17%, 14%, 2%, 37%, and 30%, respectively (Leelaudomlipi 2002).

Commonly performed partial hepatectomies in mice remove 60% (ML+LL), 75% (ML+LL+IRL) and 83% (ML+LL+IRL+CL) of the liver parenchyma (Inderbitzin 2004, Inderbitzin 2006). Twenty-one days after resection of the ML and LL in the mouse, the

remaining lobes IRL, SRL, AC, and PC represent 55%, 26%, 9%, and 10%, respectively (Nikfarjam 2004).

Figure 12. Schematic description of partial hepatectomies in the rat (anterior view of the liver) and approximate parenchymal volumes. These values slightly change in the mouse (refer to the text). Hepatectomies ranging from 5 to 95% of total liver weight can be easily performed with high reproducibility using microsurgical techniques, since the parenchymal mass of which lobe is relatively constant. Approximately, the percentages of liver weight per lobe are: SRL 12%, IRL 10%, ML 38% (RML 25% and LML 13%), LLL 30%, AC 4%, PC 4%, CP 2-3%. In the classic 70%-hepatectomy, the left lateral (LL) and the medial (ML) lobes are removed. Isolated resections of the MLL or LLL should preferentially not be performed since cholestatic and vascular complications are more common.

The Liver Regeneration Model

The process of hepatic regeneration in rodents and humans are similar, and the results obtained from rodents are applicable to the human liver (Fausto 2001). The rat 70% hepatectomy is the most valuable and most extensively studied animal model for liver regeneration (Higgins 1931; Rodriguez 1999; Fausto 2005).

The hepatic regeneration process is triggered promptly after injury, and in the rat, the DNA replication begins as early as 16 hours after resection. After a 70%-hepatectomy in the rat, the weight of the liver remnant at 24 and 72 hours is 45% and 70% of the original liver weight, respectively. Between 7 and 14 days, the liver volume is 93%, and by day 20 it completely recovers its original volume by hyperplasia of the remaining lobes (Higgins 1931). Also in humans, the regeneration process occurs quickly. The liver mass doubled at 7 days in the donor liver and 14 days in the recipient after right-lobe transplantation. Donor and recipient livers reached their original weight by 60 days after surgery. However, despite recovery of parenchymal weight the regeneration and remodeling processes continue.

The speed of liver regeneration is proportional to the amount of hepatic tissue resected. (Marcos 2000). Interestingly, it has also been shown that the regenerative capacity of individual remnant lobes is significantly different (Inderbitzin 2006). In addition, too large (>85%) or too small (<30%) resections may result in slow cell proliferation (Fausto 2001).

Models for Assessment of Hepatic Metastasis

Models of hepatectomy have been used in studies of liver metastasis after direct hepatic inoculation, or after intraportal or intra-splenic injection of tumor cells. The induction of tumor by carcinogens in the rat with spontaneous liver metastases closely mimics the natural history of colon cancer. However, only a low yield of primary cancer, e.g., colonic cancer (in less than 50% of cases) and liver metastases (approx. 25%) is obtained after 6 months of latency. Direct intraportal injection of colon carcinoma cells is the most frequently used model. Although it bypasses the natural evolution of colon cancer, this simple model produces liver metastases 6 weeks after injection of tumor cells in up to 100% of cases. This model has been used to study tumor biology, tumor induced angiogenesis, surgical and adjuvant therapy for liver metastasis, as well as the influence of hepatic regeneration on reactivation of dormant metastases and tumor growth (Panis 1990).

In this model, 8 weeks after injection of colon carcinoma cells (DHD K12 cells) into the portal vein of BD IX rats, 60% of animals did not show apparent liver metastases. However, after a 70% hepatectomy, 12 weeks after the injection of colon carcinoma cells, 62% of these animals developed macroscopic metastases compared to 20% in sham operated controls. This means that liver micrometastases may have been present at 8 weeks and had not developed until stimulation by liver regeneration after hepatectomy (Panis 1990; Panis 1992). In cases of random spread of hepatic metastases, tumorectomy alone, non-anatomical resections (wedge resection), and segmentectomies may be employed.

Models of Acute Liver Failure

Models of acute liver failure are important to investigate the underlying molecular mechanisms and to test liver-support strategies. These models are divided into: toxic-induced, surgically induced (partial hepatectomy, clamping) or mixed. Surgical models of acute liver failure are divided into: total hepatectomy, partial hepatectomy, and partial or total liver devascularization (Rahman 2000).

Small-for-Size Syndrome

Models of hepatic resection and partial liver transplantation have also been used to study small for size syndrome. One study showed that immediately after classical 70% hepatectomy the hepatic arterial blood flow decreased (from 0.4 ± 0.12 to 0.33 ± 0.03 ml/min/g liver), the portal venous inflow increased (from 0.90 ± 0.30 to 2.20 ± 0.26 ml/min/g liver), the total hepatic blood flow increased (from 1.30 ± 0.39 to 2.53 ± 0.26 ml/min/g liver), and the portal pressure elevated (from 8.80 ± 0.7 to 11.9 ± 1.7 cm H₂O) (Lin 1990).

Portal hyperperfusion in small-for-size livers, in cases of major hepatic resections or transplantation, may seriously impair postoperative liver regeneration. The altered physiologic state results in increased portal blood flow, which induces shear stress and damage to sinusoidal endothelial cells and Kupffer cell activation which contributes to acute liver failure (Glanemann 2005). In these models, a major hepatic resection (e.g., 90%) or a total hepatectomy followed by small-for-size graft (25 to 30% of original volume) liver

transplantation are performed (Panis 1997; Glanemann 2005; Yao 2007; Zhong 2007). When transplantation is used as a model, a classical 70% hepatectomy is performed in the donor animal before harvesting the organ.

Following a 70% resection, nearly 100% of rats survive (Emond 1989). Larger resections result in hyperperfusion of the remnant liver and ischemia/reperfusion injury (small-for-size syndrome) with subsequent massive fatty change, congestion, and centrilobular necrosis (Panis 1997). Panis and colleagues showed increased necrosis following progressive increase in the hepatectomy extent (Panis 1997). Following a 75%, >85%, and >90% hepatectomy, survival rates were 100%, 18% and 0%, respectively. The increased mortality associated with large resections can be reduced by administration of glucose solution (Gaub 1984; Roger 1996). The survival rate of 90%-hepatectomy could be increased from 5% to 60% by addition of glucose 20% in drinking water (Gaub 1984, Emond 1989). Roger introduced the 95% hepatectomy with survival rate of only 20%, even with addition of glucose (Roger 1996). Madrahinov reported a 1-week survival rate of 100% and 66% following a 90% and 95%, respectively. However, in this study, all animals died of liver failure within 4 days after a 97% hepatectomy (Madrahimov 2006).

Eguchi et al. described a model of resection-ligation (Eguchi 1997). In this model, the left lateral and median lobes (68%) were resected, and the ligated right liver lobes (24%) were left in place; the caudal lobes (8%) were left intact. They reported a 90% mortality rate at 48hr after surgery, proceeded by grade III encephalopathy beginning at 22–24hr, and associated with deterioration of liver function tests, and increased ammonia and lactate levels.

In the mouse, Inderbitzin et al. showed that liver regeneration was excellent in up to 75% partial hepatectomy. On the other hand, 83% resection resulted in animal death after 2–4 days (Inderbitzin 2006). However, in this experiment only one subcutaneous dose (1ml) of glucose 1% was given postoperatively. One other study showed that all of the 70%-hepatectomized mice were alive at 1 week, but the 90%-hepatectomized mice all died within 24 hours after hepatectomy despite free access to glucose 10% (Makino 2005).

Techniques of Liver Resection

Liver resections in rodents are very well tolerated with minimal operative mortality. So far, four techniques for hepatic resection in rodents have been described:

1. *The classical technique* (Ligature *en-bloc* at the base of the lobe). Although this is the most commonly used technique, it carries the highest risk for injuries because the mass ligature may compromise elements of other pedicles. The risk of vena cava stenosis and liver congestion is particularly high when only one ligature for both the median and left lateral lobes' pedicles is performed, due to compression of the vein after mass ligation. This procedure can be performed through conventional (open), or laparoscopic technique (Higgins 1931; Ralli 1951; Krahenbuhl 1998). However, the laparoscopic approach does not seem to provide any advantage over other techniques. It is time-consuming and requires specialized and costly equipment.
2. *The hemostatic clip technique*. This is a slight modification of the classical technique, where titanium clips are applied to the pedicle instead of using sutures. This procedure is fast, but is associated with similar complications of the mass ligature

technique. In addition, concerns with interference on the regeneration process have been raised, although this has not been confirmed in subsequent investigations (Schaeffer 1994; Nikfarjam 2004).

3. *The vessel-oriented parenchyma-preserving technique.* This technique reported by Madrahimov requires no prior ligation at the liver hilum (Madrahimov 2006). Sequential piercing sutures, proximal to clamp, are positioned according to topographic vascular anatomy. Although this technique is faster than the microsurgical technique (described below), it may cause injury of other vascular branches since vessels are not individually visualized. Therefore, it is not recommended for resection of the right or left segments of the median lobe.
4. *The vessel-oriented microsurgical technique.* This technique, first reported by Kubota et al., is similar to the technique for clinical hepatectomies (Kubota 1997). The portal vein and hepatic artery branches are ligated prior to the resection of the lobe, and the hepatic veins are ligated within the lobe during parenchyma resection (in a similar fashion of the parenchyma preserving technique). The advantages of this technique are reduced risk of bleeding from the stump and reduced risk of vena cava constriction. It is also more appropriate for segmental hepatectomies, e.g., resection of the right or left portion of the median lobe, after delineation of the ischemic line following the ligature. The disadvantages include requirement of microsurgical skills and equipment, risk of portal vein injury during dissection, and its more time-consuming nature (Kubota 1997).

Liver Resections Using Microsurgical Techniques

Hepatic resection may be improved by microsurgical techniques because they permit individualized dissection and ligature of small vascular and biliary branches of the median and left lateral liver lobes, while avoiding damage to the remaining lobes and other complications (tear of extra-hepatic biliary tree and biliary fistula, vena cava stenosis). This contributes to reduce complications and make results more homogenous.

To our knowledge, the first description of the use of microsurgery to perform hepatectomy in rodents was from Holmin in 1982. However, he used a microscope (10x magnification) not to perform the parenchymal dissection and resection but to perform a portocaval shunt before a total hepatectomy in a rat model of acute liver failure (Holmin 1982). In fact, Rodriguez in 1999 was the first to report the use of a microscope to perform vascular isolation of individual pedicles for partial hepatectomies in the rat (Rodriguez 1999). In a study from Higgins, utilizing the classical technique without optical magnification, the postoperative mortality rate following a 70% hepatectomy was 25% (n = 220), Rodriguez reported no morbidity and 0% mortality (n = 20) utilizing the microscopic approach (Higgins 1931, Rodriguez 1999). Another study published by Greene et al. obtained 96% survival rate after 70% hepatectomy in the mouse model using magnifying operative loupes (Greene 2003).

Non-Conventional Anatomical Resections

Microsurgical techniques permit anatomical segmentectomies. Isolated resection of the left lateral lobe or median lobe as well as segmental resections of the left or right portion of the median lobe represents a technical challenge. Although the left lateral lobe is easily resectable, care should be taken to avoid ligation of the branches to the median lobe, which will lead to ischemia of the lateral aspect of this lobe. In addition, some biliary ducts of the left median lobe may drain into branches of the left lateral lobe, implying the existence of a biliary functional interrelationship between the left median lobe and the left lateral lobe. Thus, the isolated resection of either the left lateral lobe or median lobe may sometimes result in cholestasis of the adjacent lobe (Lorente 1995; Lorente 1995).

Figure 13. Ligation of the inferior pedicle of the median lobe of the rat liver. This pedicle (shown here suture ligated) supplies the right portion of the right median lobe (RML). The superior pedicle of the median lobe is depicted here by the asterisk (*). C and D) Ligation of the superior pedicle of the median lobe (in Figure C, magnification 20X). The superior pedicle of the median lobe supplies the left portion (LML) and is shown here suture ligated (arrow). The location of inferior pedicle of the median lobe is marked here by the asterisk (*). Shortly after these ligations, an ischemic line (dotted line) on the medial lobe ML (B and D) equivalent to the Cantlie's line can be seen on the falciform ligament insertion line, from the suprahepatic vena cava to the main liver fissure (umbilical fissure). The resection of the RML (equivalent in humans to segments IV, V and VIII) and the LML (equivalent to segment III in humans) can only be performed using microsurgical techniques. Dissection and ligation should be very careful to avoid injuries of the vascular and biliary system of the adjacent segment. Scale bar 0.6cm.

Isolated resection of the right or left sectors of the median lobe and resection of the superior or inferior aspect of the left lateral lobe requires delicate dissection of the hilar region and intrahepatic ligation of individual vascular and biliary branches. For resection of the right portion of the median lobe (which represents segments IV, V and VIII in humans

according to Kongure), the inferior pedicle of the median lobe (which is the first portal branch to the median lobe together with the arterial branch) should be ligated *en-bloc* and divided (Kogure 1999). The superior pedicle of the median lobe lies close to the superior aspect of the superior right lobe. For resection of the left portion of the median lobe (which represents segments III in humans), the second portal branch (superior pedicle) to this lobe should be ligated and divided (Kogure 1999). It lies in close proximity to the hepatic vein draining the left portion of this lobe and can be easily visualized after removal of the overlying peritoneum (Figure 13).

The left lateral lobe also has two vascular pedicles (inferior and superior) and two independent venous drainages, which permits anatomical segmentectomies in this lobe (Lorente 1995; Madrahimov 2006; Martins 2007). The first vascular pedicle, inferior to part of the LLL, lies on the bottom of this lobe while the second is located superior-posterior and close to the left hepatic vein (Figure 14). In either one of these segmentectomies (left medial or right medial), after ligating the vascular pedicle, the ischemic line can be visualized on both surfaces of the liver. Then, the parenchyma can be resected 2 mm away from the perfused area. These segmentectomies are more difficult to perform in the mouse because the structures are much smaller and more delicate (the mouse is in average 20 times smaller than a rat).

Figure 14. A-C) Ligature of the inferior vascular pedicle of the left lateral lobe (arrow) of the rat liver demarcates an ischemic line (dotted line) on the anterior (B) and posterior (C) surface of this lobe. This ischemic area represents $\frac{3}{4}$ of the LLL and either represents an individual segment, equivalent to the human segment III, or is a subsegment of the LLL. D-F) After ligature of the inferior pedicle (arrow), the superior vascular pedicle was ligated (*) and the whole left lateral lobe turned to be ischemic. The area supplied by the superior pedicle may be the equivalent of the segment II in humans. Magnification 2X.

The individual isolation of the portal vein branch from the arterial branch and bile duct may be necessary in some experiments that investigate individual effects of arterial or portal isolation. This dissection is difficult to perform, since they are fragile and closely adherent and surrounded by connective tissue. One maneuver that helps this dissection is flushing pressured saline solution with a syringe close to the pedicle elements. The author successfully

used this technique to perform vascular dissection in a kidney transplantation model (Martins 2006). Hydrodissection can display the correct plane of dissection while reducing risks of injuries.

The main advantage of hepatectomies employing microsurgical techniques is that it is possible to perform several extents of hepatectomy, including segmental resections, while reducing the risks of vascular and cholestatic complications.

Limitations of Rodent Models of Hepatic Resections

The use of rat and mouse models in liver surgery research is limited by their small size and limited knowledge on the liver anatomy (Lorente 1995; Lorente 1995; Martins 2007). As in humans, the rat and mouse liver vasculature and biliary system show a great anatomical variability. In addition, the liver anatomy of rodents and its correlation to the human liver is not completely understood.

Table 1. Comparison of rat and human liver

Rat Liver	Human Liver
Multi-lobulated liver	Liver lobes have no clear anatomical divisions (liver appears to be single anatomic unit)
Long celiac trunk	Short celiac trunk
Inferior vena cava is intra-hepatic	Inferior vena cava is retroperitoneal
Gallbladder absent	Gallbladder present
CBD lies to the left of portal vein and has a long intra-pancreatic trajectory	CBD lies to the right of the portal vein and has a short pancreatic trajectory
Collateral arterial circulation is common (Hepato-esophageal artery)	Collateral arterial circulation is uncommon
Intercommunications between portal and venous pedicle is common	Vein intercommunications is not common
Divisions of the caudate lobe is distinct	Caudate lobe has no clear-cut anatomical subdivisions
Trifurcation of the portal vein	Bifurcation of the portal vein
“Left-“ and “right liver” have similar volume	“Right liver” volume is superior to the “left liver”

The best anatomical model proposed so far is from Kongure and colleagues. In this model, the whole left lateral lobe corresponds to the human segment II and the left median lobe corresponds to segment III. However, his study did not consider that the left lateral lobe has two individual vascular supplies and drainages, which are prerequisites for segmental denomination. Based on topography and proportions, the small superior segment of the left lateral lobe could be considered equivalent to the human segment II and the larger inferior segment to the human segment III. If this is the case, the left median lobe would be equivalent to the segment IV, while the right median lobe would be equivalent only to segments V and VIII. The falciform ligament in humans runs from a point to the left of the vena cava to a point to the left of the gallbladder, and the area between the falciform ligament and the Cantlie’s line (imaginary line from the vena cava to the gallbladder) represents the segment IV. Kongure proposed the equivalence of the rat segments assuming that the location of the rat falciform ligament is the same as in humans. If we consider the falciform ligament to define the nomenclature of the rat liver lobes, the left median lobe could be the equivalent to segment III because it lies directly to the left of the falciform ligament. However, in the

mouse, which is phylogenetically much closer to the rat, the falciform ligament lies between the vena cava and gallbladder, located in the main liver fissure (Figure 2). The main fissure marks the division of the medial lobe into left and right portions. Similarly, to the mouse, the rat falciform ligament runs between the vena cava and the main liver fissure (the rat has no gallbladder) and may have the equivalent position to the Cantlie's line in humans. Taking these facts into consideration, the rat left median lobe could be the equivalent to segment IV, and not to segment III.

One pitfall of segmentectomies of the right or left portion of the median lobe is that they may be associated with liver congestion in the animals in which the vein draining the left portion of the median lobe joins the left hepatic vein (draining the left lateral lobe) to form a common trunk before draining to the vena cava. In addition, some biliary ducts of the left median lobe may drain into branches of the left lateral lobe, implying the existence of a biliary functional interrelationship between the left medial lobe and the left lateral lobe. Thus, the isolated resection of either the left lateral lobe or median lobe may sometimes result in cholestasis of the adjacent lobe (Lorente 1995; Lorente 1995; Martins 2007).

Results obtained in rodent models cannot be fully translated to humans because the kinetics of liver regeneration in different species is not the same. The amount of remnant hepatic tissue compatible with life in rodents seems to be less than in humans. While in humans the maximum amount of liver that can be tolerated is 70–80% of the original volume, rodents can survive even after a 90–95% hepatectomy (Shirabe 1999; Fan 2000; Renz 2000; Leelaudomlapi 2002; Schindl 2005; Madrahimov 2006). Table 1 compares rat to human livers.

Models of acute liver failure based only on reduction of liver mass (hepatectomy) are in general not reversible and not associated with the same level of tissue damage and necrosis commonly seen in clinical setting (caused by toxic and viral agents). In order to overcome this problem one can subsequently add liver stress after liver resection with tissue ischemia (clamping) or toxic agents. Another model proposed a combination of major liver resection with hepatocyte transplantation as a possible approach to recover liver function (Roger 1996).

CIRRHOSIS, PORTAL HYPERTENSION MODELS, AND PORTOCAVAL SHUNTS

Portal hypertension models are important to the study of the pathophysiology of liver disturbances, liver regeneration, complications and treatment approaches. The models can be categorized as toxic (e.g., carbon tetrachloride (CCl₄), alcohol), nutritional (feeding choline deficient or methionine deficient diet), surgical (partial portal vein ligation, bile duct ligation), immunological (heterologous serum, schistosomiasis), and genetic (Rhino mice) (Tsukamoto 1990; Orloff 2001; Abraldes 2006; Abraldes 2006) (Table 2). Other toxic agents that have been used in diverse animal models to produce cirrhosis, include carbon tetrachloride, dimethylnitrosamine, thioacetamine, monocrotaline, and alcohol (Groszmann 1982; Proctor 1984; Tsukamoto 1985; Dashti 1989; Perazzo 1999). Rodents are the most utilized models because of low cost and easy handling. The most common model of cirrhosis is the CCL₄ model. It can be given via injection, inhalation, or orally. Liver cirrhosis is expedited by giving phenobarbital added to the drinking water (cirrhosis obtained in 4 to 6 weeks).

Acute administration of carbon tetrachloride induces acute hepatitis. Continuous administration induces chronic liver injury that leads to cirrhosis. Route of administration varies among laboratories, but the most effective are oral, intraperitoneal or inhalatory routes. Twelve to 15 weeks after CCl₄ administration, the rats develop micronodular cirrhosis (Proctora 1982; Kobayashi 2000; Hernandez-Munoz 2001; Constandinou 2005; Abraldes 2006).

Cirrhosis induced by thioacetamide (TAA) is another widely used model of toxic cirrhosis. The toxin affects both perivenular and periportal areas. It has been used in rats and mice (Li 2002, Okuyama 2005). TAA can be administered in drinking water or by intraperitoneal injection (Li 2002; Luo 2004; Popov 2006). Intraperitoneal injection offers much more consistent results (Popov 2006). This model develops macronodular cirrhosis with portal hypertension in 12 weeks (Abraldes 2006).

Table 2. Experimental Models of Hepatic Fibrosis/Cirrhosis.
Adapted from Tsukamoto H, et al.

Species		Method	Fibrosis	Cirrhosis
Toxic • Carbon tetrachloride (CCl ₄) • Dimethylnitrosamine (DMNA) • Thioacetamide (TAA)	Rats	Subcutaneous injection, 0.1-0.2ml/100g of body weight twice weekly	>6 weeks	>12 weeks
	Rats	Inhalation twice weekly plus sodium phenobarbital in drinking water Intraperitoneal injection 3 days weekly	>1-2weeks	>4 weeks
	Rats	Oral administration 2 days weekly TAA in drinking water (300mg/L)	>4 weeks	>13 weeks
	Dogs			
	Rats		>3-4weeks >2-3 months	>13 weeks >3months
Nutritional	Rats/mice	High-fat/low-choline, low-protein diet	>6weeks	>12-24 weeks
Immunologic • Heterologous serum • Bacterial cell wall • Marine schistosomiasis • Endotoxin	Rats	Low-protein/low-methionine diet plus ethionine (0.5%)	>4weeks	>12weeks
	Rats	Swine serum, intraperitoneal injection twice weekly	>5 weeks	>10 weeks
	Rats	Streptococcal cell wall, single intraperitoneal injection (20mg/g of body weight)	>6weeks	--
	Mice	Subcutaneous injection, 50 <i>cercariae</i> of <i>Schistosoma mansoni</i>	>6weeks	--
	Rabbits	<i>E. coli</i> endotoxin injection into the common bile duct (0.2/mg) followed 24 h later by 0.1/mg via marginal ear vein	--	>9 days
Biliary	Rats	Common bile duct ligation	>4 weeks	--
	Dogs	Common bile duct ligation	>4 weeks	--
	Monkeys	Common bile duct ligation	>2months	>6 months
Alcoholic	Baboons	Ethanol-containing liquid diet, <i>ad lib</i> Continuous intragastric infusion of ethanol and a high-fat diet	>6 months	>24 months
	Rats		>3 months	--
Genetic	Rhino mice	Mutant with the anatomical recessive gene	>6 months	--

Dimethylnitrosamine induced cirrhosis (DMNA) DMNA is another hepatotoxin that induces hepatocellular necrosis. After continuous administration (generally intraperitoneal) the rats develop fibrosis with portal hypertension, which may be present as early as 5 weeks despite the fact that animals do not have cirrhosis nor features of hyperdynamic circulation (Veal 2000). Overt cirrhosis with ascites develops in 13 weeks (Jenkins 1985; Tsukamoto 1990).

Diet induced cirrhosis is seen in diets deficient in choline and methionin, or a diet with low protein and choline and enriched with fat, induces liver steatosis associated with marked oxidative stress that induces inflammation and fibrosis (Tsukamoto 1990; Nanji 2004). Cirrhosis develops after 12 to 24 weeks.

Partial Portal Vein Ligation

Partial portal vein ligation model (PVL) has been widely used in the study of the pathophysiology of portal hypertension. This model has been developed in rats, mice, and rabbits (Vorobioff 1983; Colombato 1992; Castaneda 2000; Iwakiri 2002; Fernandez 2004). The portal vein is freed from surrounding tissue after a midline abdominal incision. A ligature (silk 3-0) is placed around a blunt-tipped needle lying along the portal vein. Subsequent removal of the needle yields a calibrated stenosis of the portal vein that has the diameter of the needle. In the conventional rat PVL model a 20G needle is used (0.889 mm diameter) (Vorobioff 1983, Colombato 1992, Castaneda 2000). By using needles of greater caliber, less severe stenosis and thus less severe degrees of portal hypertension are induced (Lozeva 2004, Abraldes 2006). The diameters of the needles and resulting levels of stenosis are as follows: 16G: 1.651mm, 18G: 1.270 mm, 20G: 0.889 mm. The conventional needles for mice and rabbits are 27G (Iwakiri 2002; Fernandez 2004).

Bile Duct Ligation

Cholestasis is a common pathological condition that can be reproduced in rodents by surgical ligation of the common bile duct. Common bile duct ligation (CBDL) is a model of secondary biliary cirrhosis. Evaluation of the various time-related changes after BDL is paramount for the interpretation of available data as well as for the design of future studies.

A Systematic Chronological Evaluation of Hepatocellular Injury and Proliferation, Hepatic Inflammation or the Development of Liver Fibrosis Following BDL

The intervention consists of the isolation of the common bile duct followed by a double ligature. The first ligature is made below the junction of the hepatic ducts and the other above the pancreatic duct. The portion of the bile duct between the two ligatures can be resected to avoid recannulation. Mortality is high after the fifth week (20%). The use of prophylactic antibiotics (Ampicilin 100 mg/Kg s.c. or similar) before surgery and weekly administration of

vitamin K (50 mcg subcutaneous) notably improve the survival of CBDL rats. At 2 weeks rats develop mild portal hypertension and at 4 weeks severe portal hypertension, hyperdynamic circulation and portal-systemic shunting of 30–60% (Franco 1979; Beck 1995).

Serum levels of ALT and biliary infarcts increased after BDL, peaking at days 2 and 3 respectively. Following acute or chronic tissue loss, hepatocytes mount a proliferative response. BDL induced a distinct peak of hepatocellular proliferation at day 5, approximately 48 hours after the peak of histologically detectable hepatocellular injury. After the initial peak on day 5, continuous proliferation was observed at a low level. The proportion of continuously proliferating hepatocytes is in the range of 1 to 3% (Ezure 2000; Georgiev 2008).

Figure 18. Liver injury was determined by A) serum alanine aminotransferase (ALT) levels. Serum levels of A) conjugated and unconjugated bilirubin and B) alkaline phosphatase. Percentage of liver surface stained with Sirius red. Values are mean (s.e.m.) for five to six individual animals per time point. * $P < 0.050$ versus sham-operated control (two-tailed Mann–Whitney test). Adapted from Georgiev, et al.

Serum levels of alkaline phosphatase and bilirubin are classical markers of obstructive cholestasis in the clinical setting (Pratt 2005). Raised serum levels of alkaline phosphatase are due to *de novo* synthesis in the liver (Kaplan 1970). Interestingly, serum levels of alkaline phosphatase were not found to increase progressively after BDL. A first peak during the acute phase was followed by decreasing levels from day 3 to day 7, indicating that the acute injury triggers a massive production and release of this enzyme.

BDL results in an increase in serum markers of cholestasis such as bilirubin and alkaline phosphatase. Conjugated and unconjugated bilirubin levels increased steadily and in parallel until day 7 and remained high thereafter (Figure 18). Alkaline phosphatase production is

induced after BDL in rats and its release from the canalicular membrane of hepatocytes is modulated by bile acids. Serum levels of alkaline phosphatase showed a biphasic course, peaking on day 2 and then increasing steadily from day 7 onwards; cell proliferation reached a steady state in the biliary epithelial cells (BEL) compartment by day 1.

Neutrophils contribute to cholestatic liver injury after BDL for 3 days, whereas Kupffer cells are believed to abrogate acute cholestatic liver injury through the release of interleukin 6 (Gujral 2003; Gujral 2004; Gehring 2006). Little attention has been paid to the role of lymphocytes, which are known to modulate liver fibrosis in other models of liver disease (Wynn 2004; Novobrantseva 2005). The histological analysis indicated that both B and T cells were present in the portal tracts of mice after day 5 of BDL. Interestingly, both cell types accumulated mainly during the phase of collagen deposition and thus may also be involved in the process of fibrogenesis following BDL (Gujral 2003; Georgiev 2008).

Figure 19. Overview of dynamic changes following bile duct ligation in mice. BD, bile duct; BEC, biliary epithelial cell; HC, hepatocyte; PMN, polymorphonuclear leucocyte.

This model develops biliary fibrosis-cirrhosis in 4 to 6 weeks. Histology shows marked cholangiolar proliferation and expansive portal fibrosis (Figure 19), but the architectural disturbances typical of cirrhosis are seldom found (Kountouras 1984). See Figures 18–19.

PORTOCAVAL SHUNTS

In 1877, Dr. Eck described experiments using portacaval shunt in dogs (Eck fistula) (Rocko 1985). Lee and Fisher in 1961 perfected the technique of portocaval shunt in the rat so that it became a reproducible model (Lee 1961). Before this technique was established, others have tried to interpose prosthetic tubes between the portal vein and IVC with high mortality rates (Whitaker 1946; Bernstein 1954).

Technique

The peritoneum over the inferior IVC is cut. Then, with a curved forceps the vena cava is mobilized from the inferior aspect of the liver to the right renal vein. Next, the peritoneum covering the portal vein is open, the portal vein is mobilized, and the gastroduodenal vein is doubly ligated and cut. A small vascular spoon clamp is placed on the IVC between the liver and the renal veins, partially obstructing its flow. A 4–5 mm incision is made on the IVC and flushed with heparinized saline. Next, the distal portal vein is ligated with 6-0 silk tie flush to the liver. The proximal portal vein is clamped with a small vascular clip, and the portal vein is cut above the stump of the gastroduodenal vein. The portal vein lumen is flushed with saline and two 7-0 prolene sutures are placed on the corners. The anastomosis is completed on a running fashion. First the posterior wall, followed by the anterior wall. After completion of the anastomosis the caval clamp is released and hemostasis accomplished with gentle compression with cotton swabs. The portal clamping time is of critical importance for the success of the procedure and it should be less than 30 minutes (see Figures 15–17) (Castaing 1980).

PANCREATITIS MODEL

A better understanding of the underlying pathophysiology of severe acute pancreatitis may lead to more targeted therapeutic options, potentially leading to improved survival. Animal models of acute pancreatitis are therefore an essential investigative tool for these aims to be achieved.

There are several models of acute pancreatitis, and they can be divided as invasive and non-invasive (Su 2006). Non-invasive models of acute pancreatitis are: hormone-induced, alcohol induced, immune-mediated, diet-induced, gene knockout and L-arginine; while invasive models are: and invasive models including closed duodenal loop, antegrade pancreatic duct perfusion, biliopancreatic duct injection, combination of secretory hyperstimulation with minimal intraductal bile acid exposure, vascular-induced, ischemia/reperfusion and duct ligation (Su 2006).

Independent of the model used, the pathophysiology event of experimental acute pancreatitis consists of the activation of pancreatic enzymes within acinar cells, the release of these activated enzymes in the interstitium, the autodigestion of the pancreas, and the release of activated pancreatic enzymes and other factors into the circulation that result in the development of systemic effects. An ideal model of acute pancreatitis should be easily reproducible, be able to adjust the severity of the inflammation and, and the morphology and pathophysiology should resemble that of the human situation.

Animal models of acute pancreatitis, induced by acute ethanol application alone, have been difficult to produce and require prior sensitization with other agents to allow significant pancreatic damage to occur (Letko 1991; Siech 1991; Quon 1992; Foitzik 1994; Luthen 1994; Andrzejewska 1998). Existing alcohol-induced models are relatively simple and cheap to perform. Acute ethanol administration selectively lessened pancreatic blood flow and microcirculation, suggesting that the effect of alcohol might increase ischemia damage during the evolvement of acute pancreatitis with or without underlying chronic disease. Another

advantage of this model is that it allows alcohol to directly damage the pancreas by the influence of toxic ethanol metabolites, and perhaps by limitations of pancreatic regeneration. Reproducibility, however, has not been successfully achieved. Furthermore, there is a lack of correlation with the clinical setting.

Closed Duodenal Loop Model

Experimental acute pancreatitis in animals may be produced by creating a closed duodenal loop (CDL). This technique involves surgically closing above and below the duodenal papilla while bile is diverted into the jejunum via an implanted cannula. Evidence of edema, hemorrhage and necrosis of the pancreas developed within 9 to 11 hours. The model was first developed by Pfeffer et al. (Pfeffer 1957). It is relatively simple and is reproducible.

Since the permanent ligation of the duodenum often caused death of the animal within a short period, some investigators have attempted temporary ligation of the duodenum in rats (Ferrie 1978, Orda 1980). This allowed them to examine the progression of acute pancreatitis at an extended time and to investigate potential therapies. In a study by Orda et al., the authors injected a mixture of sodium taurocholate and trypsin into a temporary CDL to induce acute pancreatitis in rats (Orda 1980). They found that the acute pancreatitis induced was mild, associated with a mortality rate of 45%.

Antegrade Pancreatic Duct Perfusion Model

The main pancreatic duct can be made permeable by the perfusion of glycodeoxycholic acid (GDOC) along the main pancreatic duct. Other methods include the administration of intragastric ethanol, the stimulation of pancreatic secretion into an obstructed duct, or causing acute hypercalcemia (Farmer 1983; Wedgwood 1986; Widdison 1992).

The advantages of the pancreatic duct perfusion model are its reliability and reproducibility. The severity of the acute pancreatitis may be varied within well-defined time intervals according to the volumes and perfusion pressures. The etiology and the morphological changes closely resemble the human situation. This model is suitable for studying the early pathophysiology and subsequent progression of the disease. It is the ideal model to assess potential therapeutic agents. The major disadvantage of this model is its complexity (ductal cannulation and perfusion). Other disadvantages include the need to use large animals.

Biliopancreatic Duct Injection Model

Various compounds have been infused into the pancreatic duct to induce acute pancreatitis (EL 1901; Beck 1964; Papp 1966; Sum 1970; Aho 1980). Following a duodenotomy, a retrograde injection of bile salts (with or without activated pancreatic enzymes) into the pancreatic duct at the ampulla leads to severe acute pancreatitis. The severity of the disease can be manipulated by changing either the pressure or the concentration of bile salt used. Acute severe pancreatitis develops within 2 to 24 hours and is

characterized by edema, necrosis and hemorrhage. Almost any form of detergent injected into the pancreatic duct under pressure will cause acute pancreatitis in laboratory animals such as dogs and rats (Musa 1976; Aho 1980; Aho 1980; Aho 1983). One of the best standardized compounds to use to develop acute pancreatitis is sodium taurocholate. Infusion of 0.2 ml/kg of 3%, 4.5% or 5% solution induced acute hemorrhagic pancreatitis with 72 hour mortality rates of 24%, 71% and 100%, respectively (Aho 1980; Aho 1980; Aho 1983). This model is appropriate for studies of systemic issues.

The retrograde injection of bile salts into the pancreatic duct of animals is an easy, effective and reproducible model for creating a severe, rapidly evolving and lethal variety of acute hemorrhagic pancreatitis.

It is also technically challenging to control constant pressure recordings and hence produce a standard degree of injury. Another disadvantage of this technique is the injection pressure with which the solution is applied to cause severe acute pancreatitis (Arendt 1993).

Ischemia/Reperfusion Model

In 1995, Hoffman et al. developed a model to study the microcirculation of the pancreas in the rat after complete (interruption of arterial blood supply to the pancreas) and reversible ischemia of the pancreas using intravital fluorescence microscopy (Hoffmann 1995). Complete ischemia of the pancreas was achieved by isolating arteries from surrounding tissue of gastroduodenal artery, left gastric artery, splenic artery and caudal pancreaticoduodenal artery. Complete but reversible ischemia of the pancreas was induced by occluding the four vessels using microvascular clips. The clips were taken out at 30 minutes, 1 hour or 2 hours after ischemia to produce reperfusion.

The duration of ischemia and of reperfusion is responsible for the severity of post-ischemic inflammatory reaction. In addition, there was a rise in the concentration of serum amylase after 1 and 2 hours of ischemia (Hoffmann 1995). Similar results were observed by another group after 2 hours of ischemia and 4 hours of reperfusion (Broe 1982).

Duct Ligation Model

Acute pancreatitis may be induced by ligating the distal bile duct at the level of the duodenum (Baxter 1985). This creates an early development of acute pancreatitis, obstructive jaundice and cholangitis in the rat. The duct ligation model was developed in an attempt to resemble the clinical situation of gallstones, motility disorders of the sphincter, edema and strictures at the papilla, tumors of the papilla, and parasites impacting the terminal biliopancreatic duct. Surgical ligation of the pancreatic duct alone has not been successful in inducing acute pancreatitis.

Most laboratory animals developed chronic lesions in the pancreas characterized by atrophy and apoptosis of acinar and ductal tissue but not significant necrosis or inflammation (Walker 1987). The ligation of the pancreatic duct in rodents has become an established model for chronic pancreatic atrophy and is often used for studying pancreatic regeneration (Lerch 1993; Lerch 1994). Ligation of this common biliopancreatic duct in the rat, however, causes a clinical syndrome resembling the multi-system organ failure observed in man.

Ligation of the pancreatic duct alone, bile and pancreatic duct separately, or the common biliopancreatic duct leads to severe acute pancreatitis with mortality rates approaching 100% within 2 weeks of induction (Senninger 1986; Cavuoti 1988) (See Table 3).

Models of chronic pancreatitis in rodents do not closely resemble the same process in humans. Prolonged feeding with ethanol to rodents does not induce chronic pancreatitis and alternative approaches have been suggested (Goto 1995; Van Laethem 1996; Puig-Divi 1999; Vaquero 1999; Gonzalez 2011).

Table 3. Summary of non-invasive experimental models of acute pancreatitis

Model	Advantages	Disadvantages	Clinical relevance
Hormone-induced	• Causes acute pancreatitis in animals (e.g., rats, mice, dogs, Syrian hamsters) • Can induce acute pancreatitis by various routes such as IV (preferred), subcutaneous or intraperitoneal • Allows accurate control of infusion rate, thereby enabling control of timing and severity of acute pancreatitis • Useful for studying cell biology, gut endocrine interactions (secretin, CCK levels), pathogenesis of acute pancreatitis-related pulmonary pathology, systemic disease manifestation, and healing and regeneration of damaged tissue after toxic substance has been discontinued • Simple; inexpensive	• Only mild acute pancreatitis develops • Negligible mortality • High variability in course and severity of underlying acute pancreatitis; unsuitable for controlled studies	• Pulmonary injury in rats resembles early stages of ARDS in humans • Structural changes of acinar cells are similar to human acute pancreatitis • Specific changes to intracellular membrane systems of acinar cells resemble acute pancreatitis in humans • Simulates acute pancreatitis induced by anti-cholinesterase insecticide poisoning in humans
Alcohol-induced	• Useful for studying changes to pancreatic blood flow and microcirculation, effect on pancreatic acinar damage by alcohol-related free oxygen radical generation, metabolites and effect on pancreatic regeneration • Used in several animal models (rats, cats, dogs) • Various routes of ethanol administration (IV, oral, direct intragastric instillation) • Simple, inexpensive • Selectively decreases pancreatic blood flow and microcirculation • Gene knockout animals may be used to determine effect of genetic factors on development of acute alcohol-related pancreatic injury	• Animal models of pancreatitis, induced by acute ethanol application alone, have been difficult to produce significant pancreatic damage, thus require prior sensitization with other agents • Lack of reproducibility	• Lack of correlation with clinical situation
Immune-mediated	• Possible application in field of drug or toxin-induced acute pancreatitis	• Difficult to set up in laboratory • Time-consuming • Limited reproducibility • Expensive • High early mortality rate, difficult for studying pathogenesis or treatment options	• Uncertain

Table 3. (Continued)

Model	Advantages	Disadvantages	Clinical relevance
		• Development of secondary diabetes due to the involvement of islets of Langerhans	
Diet-induced	• Simplest method to study acute hemorrhagic pancreatitis • Well-established • Inexpensive	• Species-specific; may only be used in mice, whose small size causes technical difficulties	• Produces severe necrotizing pancreatitis similar to that seen in humans
	• High reproducibility • No surgical procedure involved • Mortality rate can be controlled at any desired level between 0% and 100% by modifying feeding protocol • Useful for studying pathophysiology for acute pancreatitis and potential experimental treatment by measuring survival, biochemistry, histology, changes in hematocrit, pH and blood gases • Produces hemorrhage and necrosis with lethal course • Inflammatory lesions are homogeneously distributed	• Sex-specific; female mice • Variable onset of acute pancreatitis • Requires careful monitoring to ensure that intake of CDE diet is same in different experimental groups	• Gross and histological appearance of pancreatic and peripancreatic inflammation, and clinical and biochemical course of diet-induced pancreatitis, resemble human disease • Ascites, acidosis, hypoxia, hypovolemia similar to human acute pancreatitis`
Gene knockout	• Useful for studying function or effect of specific gene of interest • Avoids use of pharmacological manipulations that often cause side effects	• Time-consuming • Expensive • Complex • Altering specific gene from time of its conception could mean that other protein expressions may result to compensate for mutation • Mutation may stimulate unforeseen phenotypic changes if gene is expressed in different tissues • Expression of two genes may overlap and the alteration in single gene may mask abnormal phenotype	• Extrapolation of experimental data to humans is difficult
L-arginine (Arg)	• High reproducibility • Ability to achieve selective dose-dependent pancreatic acinar cell necrosis • Suitable for investigating early and late phases of acute pancreatitis • Useful for investigating insulo-acinar axis, extrapancreatic organ damage and its mechanisms	• Long-term administration of Arg produces chronic pancreatitis induction	• In clinical situation, circulatory, pulmonary, renal and hepatic failure (multi-organ failure) significantly affects morbidity and mortality of acute pancreatitis

CHOLELITHIASIS

There are several models in animals that are used to study the pathophysiology and treatment of gallstones (Brenneman 1972; MacPherson 1987; Rege 1993; Cona 2016). However, there is no animal model that forms spontaneous gallstones like in humans. Most of them involve dietary manipulation. The most popular is the hamster (*Mesocricetus auratus*) model. The diet in this model consists in fat-free, high sugar, and adequate protein. Ninety percent of these animal develop gallstones in 3 months (Dam 1952). Rats are not commonly used for gallstone research because they do not have a gallbladder. Mouse models are become more popular because the extensive genetic characterization, the availability of knockout, transgenic and inbred strains. The incidence of gallstones in mice treated with lithogenic diet is very variable. While only 14% of C57BL/6J mice fed with diet consisting of 15% dairy fat, 50% sucrose, 20% casein, 1% cholesterol, 0.5% cholic acid, cellulose, vitamins and mineral for 18 weeks developed gallstones, 100% of C57L/J and A/J mice developed gallstones after the same time (Paigen 1995).

HEPATOCELLULAR CARCINOMA (HCC) MODELS

Hepatocellular carcinoma (HCC) is the most common primary malignancy of the liver. Establishing animal models of HCC is essential to study the pathophysiology of carcinogenesis, perform drug screening, and conduct various therapeutic experiments. A wide range of HCC animal models are currently available: chemically induced models, xenograft models, and genetically modified models in mice (Schotman 1998; Heindryckx 2009; Li 2011). No model, however, is ideal for all purposes. This review analyses several mouse models useful for HCC research and points out their advantages and weaknesses. Chemically induced HCC mice models mimic the injury-fibrosis-malignancy cycle by administration of a genotoxic compound alone or, if necessary, followed by a promoting agent.

Chemically Induced

Several chemical agents can promote tumor formation when administered in high doses and long duration. The advantage of chemically induced models is the similarity with the injury-fibrosis-malignancy cycle seen in humans. This makes them the favorite models for HCC research.

Diethylnitrosamine

N-nitrosodiethylamine (DEN) is often used as a carcinogenic reagent. Mouse tumors induced by DEN harbour activating mutations in the *H-ras* proto-oncogene. Administration of a high dose induces HCC after a period of latency. The time needed after a single DEN-injection to develop HCC does not only depend on the administered dose, but also on sex, age and strain of mice. A dose-dependent formation of carcinomas after a single injection (5–90

mg/kg) of DEN in 15-day-old mice is observed after 45–104 weeks. When B6C3F1 mice are exposed to a single dose of 5.0 mg/kg DEN, it takes approximately 64 weeks to develop HCC (Heindryckx 2009).

A two-stage model in which the initiation by a genotoxic compound is followed by a promotion phase is often used for inducing HCC. DEN can be used as an initiator and phenobarbital (PB) as a promoting agent. Several mechanisms might be responsible for the tumour promoting effect of PB. First, PB can increase the expression of cytochrome P-450 a 100-fold, leading to an enhanced effect of DEN. Another two-step carcinogenesis model is known as the Solt-Farber protocol (Farber 1977). In this model, initiation by a hepatocarcinogenic compound is followed by a partial hepatectomy (PH). Partial hepatectomy induces hepatic cell proliferation of the liver, leading to a fast expansion of the initiated cells (See Table 4).

Table 4. Summary of chemically induced HCC-models

	Time to develop tumors	Percent of mice with HCC	Remarks	References
Single administration	45-104 weeks (dose dependent)	80-100% in male	Poorly reproducible	Chen et al. (1993); Frey et al. (2000); Hacker et al. (1991); Park et al. (2008); Teoh et al. (2008); Zimmers et al. (2008)
Short-term administration	40-60 weeks	100% in male		Shiota et al. (1999)
Long-term administration	20-35 weeks	100% in male. 30% in female	Very aggressive tumors (H-ras mutations)	Finnberg et al. (2004)
+ Pentobarbital	20-40 weeks		B-catenin activation	Goldsworthy and Fransson-Steen (2002); Klaunig et al. (1988); Weghorst and Klaunig (1989)
+ Partial hepatectomy	4-8 weeks (in rats)			Farber et al. (1977); Klinman and Erslev (1963)
Peroxisome proliferators	50-100 weeks (dose dependent)	Depends on strain, dose and PP-agent	PP tumorigenicity in humans not known	Hays et al. (2005); Reddy et al. (1976); Takashima et al. (2008)
Aflatoxine	Early HCC in 52 weeks. High grade HCC 92-110 weeks	Considerable interstrain differences: DBA/2J: 90% C57BL/N: 25-66%	Suitable model for AFB-induced HCC in humans	McGlynn et al. (2003); Ghebranious and Sell (1998)
CCl ₄	104 weeks	50-94% (dose dependent) in male and female		Confer and Stenger (1966); Farazi et al. (2006); Weisburger (1977)
Choline deficient diet	50-52 weeks	100%	Steatohepatitis	De Lima et al. (2008); Knight et al. (2000); Liquori et al. (2009)
Thioacetamide	50-80 weeks	70-100%		

Adapted from Heindryckx F et al.

Peroxisome Proliferators

Peroxisome proliferators (ethyl clofenapate ciprofibrate, fenofibrate, clofibrate) induce hepatomegaly, peroxisome proliferation in hepatocytes and induction of several hepatic enzymes.

Aflatoxin B₁

The hepatotoxin aflatoxin B₁ (AFB), produced by certain fungi of the *Aspergillus* genus such as *Asparagillus flavum*, is known to be a hepatic carcinogen. When 7-day-old mice are exposed to 6 mg/kg body weight of AFB, in a bolus injection, HCC is developed after 52 weeks (McGlynn 2003). In 90% of the DBA/2J mice (susceptible strain for HCC) HCC occurs after AFB exposure, while only 25% of the C57BL/N mice (relatively resistant strain for HCC) develop HCC after AFB exposure.

Xenograft Models

In xenograft models, the tumors are formed by injecting human cancer cells from a lab culture in immune deficient mice. Athymic (nude) or severe combined immune deficient (SCID) mice are often used as hosts. Tumor xenografts can be established either by direct implantation of biopsy material or by inoculation of human tumor cell lines. First, the ectopic model, in which human tumor cells are injected subcutaneously in the flank of mice. Second, the orthotopic model, where tumor cells are injected intrahepatically into the mice. The advantage of xenograft mouse models is the short time span needed for the development of tumors. However, the resemblance between xenograft tumors and human tumors is rather poor. Thus, most researchers prefer to use models in which tumors arise in a background that resembles the natural history of HCC (Heindryckx 2009).

Transgenic Mouse Models

Genetically modified mouse models are engineered to reproduce pathophysiological and molecular features of human HCC (by simulating hepatitis B or C, over-expressing growth factors, or induction of oncogenes) (Heindryckx 2009). It is a unique model for assessing the effects of oncogenes either alone or in combination with other oncogenes or carcinogenic agents. The transgenic mouse models are the ones that most resemble the human HCC. Transgenic mouse models of HBV or HCV infection have provided reliable experimental proof that viral genes could initiate or promote liver carcinogenesis. Most HBV transgenic mouse models focus on the HBx gene, which encodes HBV X protein (HBx)—a transcriptional transactivator that stimulates expression of a broad range of proto-oncogenes, including c-fos, c-myc and c-jun (Li 2011).

In contrast to wild-type CD1 mice, which do not normally develop spontaneous liver tumors and have a lifespan of approximately 24 months, the majority of HBx transgenic mice died from clear cell HCC at 11 to 15 months of age.

In a similar fashion, Sell et al. constructed HBsAg transgenic C57BL/6 mice (Table 4). The 50-4 strain of these mice had a high HBsAg content in hepatocytes, premalignant changes, nodules, adenomas and HCC; exposure to diethylnitrosamine or aflatoxin accelerated the development of HCC, and produced considerably more tumor nodules in the liver.

HBV and HCV Transgenic Mice Do Not Develop Liver Cirrhosis

To avoid such problems, Yang et al. developed a modified surgical technique, in which a piece of Gelfoam is inserted into the liver incision after delivery of HCC cells. The Gelfoam both facilitates hemostasis and forms a pocket that secures the injected tumor cells (Yang 1992). These techniques have the major disadvantage of possible inadvertent tumor seeding along the needle track or into the bloodstream.

To reproduce the extensive liver disease that is associated with advanced HCC, Tang et al developed another orthotopic mouse model. HCC cells transfected with vectors carrying the gene for the [beta]-subunit of human choriogonadotropin ([beta]-hCG) were injected into the left liver lobe of SCID mice. In this model, urine levels of [beta]-hCG can be used as a surrogate marker of tumor burden (Tang 2010).

Several HCV transgenic mouse model systems have been established expressing HCV structural proteins (core, E1, E2 and p7) or nonstructural proteins (NS2, NS3, NS4A, NS4B, NS5A and NS5B) individually or in various combinations are available (Li 2011). As early as 3 months of age, HCV core gene transgenic mice developed hepatic steatosis. In mice aged up to 12 months, steatosis slowly progressed without neoplastic changes. At month 16, 25% of the male transgenic mice of the C21 line had developed HCC, but no female mice of the C21 line had developed tumors (Moriya 1998).

Animal models of spontaneous HCC development and metastasis can be used to study the mechanism of HCC progression as well as the best mode of intervention. Futakuchi et al. have established a rat model of *in vivo* HCC lung metastasis based on sequential intraperitoneal injection of diethylnitrosamine and administration of drinking water containing the carcinogen N-nitrosomorpholine for 16 weeks, by which time all animals had developed HCC. By week 23, lung metastasis had occurred in 100% of these animals (Futakuchi 1999).

Most experiments to test the effects of potential drug treatments in animal models of HCC involve the subcutaneous implantation of human hepatoma cells in immunocompromised mice (e.g., SCID mice). Although researchers have expressed doubts and criticisms about the validity of using effects on tumor xenografts to predict clinical activity

Establishing high-quality orthotopic models is, however, technically more challenging than the construction of subcutaneous xenograft models. Conventional techniques of intrahepatic tumor implantation involve direct placement of tumor fragments or injection of free tumor cells.

CHOLANGIOCARCINOMA MODELS

Several carcinogenesis models of cholangiocarcinoma (CCC) have been established in animals (Thamavit 1978; Elmore 1993; Cheifetz 1996; Sirica 1996; Lee 1997; Lai 1999; Al-Bader 2000; Yeh 2004; Sirica 2008; Yang 2011; Ko 2013; Ikenoue 2016). There are several CCC animal models: xenograft and orthotopic models, carcinogen-induced CCC model, and genetically engineered mouse model for CCA. Recent advancements in cell and molecular biology make it possible to mimic the pathogenicity of human cholangiocarcinoma using various animal models.

One model obtained CCC using Syrian hamsters being treated with *Clonorchis sinensis* or *Opisthorchis viverrini* followed by dimethylnitrosamine (DMN) (Thamavit 1978; Flavell 1983; Lee 1997). In another model Syrian hamsters were treated with DMN followed by bile duct ligation also develop CCC (Cheifetz 1996). In these models, CCC develops about 24 weeks after the initial insult, with a yield rate of only 10%. One of the better characterized rat models of CCC has been the furan model described by Sirica et al., which leads to the development of intestinal-type CCC in the caudate lobe of the liver (Elmore 1993; Sirica 1996).

Oral administration of thioacetamide (TAA) in drinking water to male Sprague-Dawley rats provides a reproducible animal model for development of CCC with a high yield rate. Drinking water with TAA 300 mg/l was administered orally. Multifocal bile ductular proliferation with intestinal metaplasia (presence of goblet cells) and increasing histologic atypia (biliary dysplasia) was observed by the 9th week of TAA administration. Biliary cytokeratin (CK19)-expressing invasive intestinal-type CCC with stromal desmoplasia was evident at the 16th week, and by the 22nd week the yield rate for CCCs had increased to 100%. The progression from normal cholangioles to biliary dysplasia to invasive CCC was accompanied by up-regulation of the proto-oncogenes c-met and c-erbB-2, tyrosine kinase receptors over-expressed in human CCCs. In the first 6 months of follow-up, no systemic metastases or tumor-related deaths were observed in this model. (Yeh 2004).

Yamada and coworkers created a mouse CCC model that transfected the biliary epithelium directly with plasmids containing oncogenes. The common bile duct located below the liver was clamped with a small animal surgical clip to prevent the injected material from rapidly flowing into the duodenum. The bile duct draining the left lateral liver lobe was identified, and a ligature (6-0 silk) was placed loosely around the duct. Another ligature was placed around the base of the gallbladder where it meets the cystic duct. Ectopic oncogene expression in the biliary tract was achieved by the SB transposon transfection system with transduction of murine constitutively active AKT and human YAP. The solution was injected into the gallbladder with enough pressure to allow the solution to distend the biliary system and reach the whole the intrahepatic biliary tree. The ligature around the left lateral liver lobe duct was then tied off so as not to allow the plasmid solution to flow from this bile duct to the common bile duct. Following plasmid injection and the left lateral bile duct ligation, the common bile duct was unclamped. The ligature around the base of the gallbladder was then tied and a cholecystectomy performed. Then, each animal was injected with 1 µg of IL-33 for 3 days (Leake 2015; Yamada 2015).

COLON CARCINOMA METASTASES

Tumor models have a key role in oncology. They are powerful tools guiding clinical research and practice (Demicheli 2001). Most transplantable tumor therapy experiments utilize ectopic (usually subcutaneous) injection of tumor cells. Ectopically transplanted tumors do not necessarily reproduce the biology of orthotopically grown tumors. The response of the primary tumor to therapy is usually what is evaluated in most tumor models. There is a need to place more emphasis on tumor models in which metastases are the primary target to therapy.

The limitations of animal models are that they usually respond better to anti-cancer therapy than in the clinical settings.

Most transplantable tumors are very fast growing (doubling times measured in days) while human tumors (with doubling times measured in months). Experimental tumors tend to be highly responsive to cytotoxic anti-cancer drugs, since this drugs target rapidly dividing cells. Most transplantable tumors are highly immunogenic because it is difficult to obtain truly syngeneic tumors. These tumors therefore become especially vulnerable to various host immune effector mechanisms.

Figure 20. Technique of portal injection to inoculate colon cancer cells DKDK12 (CAMR, Salisbury-Wiltshire, UK) in the rat liver. This reproduces the metastatic process of colon cancer. A 30G needle is used to minimize bleeding.

Figure 21. Isolated liver tumor of colon cancer cells DKDK12 (CAMR, Salisbury-Wiltshire, UK) injected in the rat portal vein 2 weeks prior.

Figure 22. Metastatic tumor of colon cancer cells DKDK12 (CAMR, Salisbury-Wiltshire, UK) injected in the rat portal vein 4 weeks prior.

Over recent years, the interest in the development of experimental models for colorectal liver metastases has increased due to the need for new adjuvant therapies to improve the treatment of both colorectal cancer and liver metastases. The induction of colon cancer by carcinogens in the rat with spontaneous liver metastases closely mimics the natural history of colon cancer but only a low yield of both colonic cancer (less than 50%) and liver metastases (approx. 25%) is obtained after 6 months of latency. Direct intraportal injection of colon carcinoma cells is the most used model. Although it bypasses the natural history of colon cancer, this simple model produces up to 100% of liver metastases 6 weeks after injection of cells. This model has been used to study morphology, neovascularization, surgical and adjuvant therapy (Panis 1991). See Figures 20–22.

In using animal models for preclinical assessment of anti-metastatic agents, it is necessary that appropriate cell lines, routes of administration and target organs used, be appropriately matched for the information sought (Chambers 1999).

Chapter 191

ANIMAL MODELS OF ACUTE GRAFT-VERSUS-HOST AND HOST-VERSUS-GRAFT RESPONSES AND DISEASE

Abraham Matar¹ and Raimon Duran-Struuck^{2,*}

¹Department of Surgery, Emory University School of Medicine, Atlanta, GA, US

²Department of Pathobiology, University of Pennsylvania
School of Veterinary Medicine, Philadelphia, PA, US

ABSTRACT

This chapter aims to provide insight into the strengths and weaknesses of animal models for the study of host-versus-graft (HVG) and graft-versus-host (GVH) responses and disease. As with any complex biological process in which animal models are used, careful assessment of their strengths and weaknesses is paramount. There is no one Universal or “best” animal model. Large animal models such as the dog, pig, or non-human primate, approximate the clinical scenario with much higher fidelity than rodents. However, rodents can be genetically manipulated with ease for the understanding of mechanistic processes that are difficult to investigate in large animals. This chapter will address both large and small animal models used to examine GVH and HVG responses/disease. We will also discuss how these approaches have reached impacted the bedside after being tested at the bench side and cage side.

Keywords: host-versus-graft (HVG), graft-versus-host (GVH) responses, mouse, dog, pig, nonhuman primate, bone marrow transplantation, liver, spleen, small bowel transplantation

* Corresponding Author’s Email: rdura@upenn.edu.

ABBREVIATIONS

ALS	anti-lymphocyte serum
BMT	bone marrow transplantation
CyA	cyclosporine A
DLA	Dog leukocyte antigen
GVHD	Graft-versus-host disease
GVHR	Graft-versus-host responses
H2	histocompatibility system
HSCT/HCT	hematopoietic stem cell transplantation/ hematopoietic cell transplantation
HVG	Host-versus-graft
KI	knockin
KO	knockout
MHC	Major histocompatibility complex
miHA	minor histocompatibility antigens
MMF	mycophenolate mofetil
MTX	methotrexate
PBCs	Peripheral blood cells
SBT	Small bowel transplantation
SOT	Solid organ transplantation
TBI	total body irradiation

INTRODUCTION

“It should be noted that marrow grafting could not have reached clinical application without animal research, first in inbred rodents and then in outbred species.”

E. Donnall Thomas, the Nobel Prizes, 1990

Animal research, as mentioned by Dr. E. Donnall Thomas in 1990 during his Nobel Prize award, has been crucial for the understanding of bone marrow transplantation (BMT) as a clinical therapy (Ladiges 1990). His studies extensively used both mice and dogs as animal models. Other important models used in BMT research are rats, cats, pigs and non-human primates. The mouse is an excellent animal model because of the similarities in physiological and pathological traits that it shares with other animals and humans. The field of BMT research has taken full advantage of these qualities, and mice have become one of the most commonly used BMT animal models.

Transplantation (organ and hematopoietic) began in the early 20th century. Several studies published between 1949–1953 (Owen 1945; Billingham 1953) documented that organs removed and immediately transplanted back into the same individual (autotransplants) were not rejected. However, organs from genetically different animals but from the same species (allografts) would eventually fail several days after transplantation. After the identification of the antigens that comprise the major histocompatibility complexes (MHC) in the 1960's, transplantation between genetically different individuals became feasible (Copelan 2006). In the veterinary medical field, it was observed that freemartin cattle (a cow

with masculinized behavior and non-functioning ovaries that is genetically a female, but is sterilized in utero by the hormones from a male twin) did not exhibit similar rejection patterns as observed in allogeneic transplantation (1945). This led to studies that hypothesized the presence of “tolerance” *in utero* which was lost soon after birth. Years later (1956–1959), the immune system was identified as the responsible mechanism for differentiating between “self” and “non-self.”

GVHD AFTER BONE MARROW TRANSPLANTATION

Mice and other rodents were first used as animal models for BMT research when scientists and physicians began investigating irradiation-induced bone marrow injury after the World War II. It was observed that after lethal total body irradiation (TBI), restoring bone marrow would rescue the animal’s immune system (Thomas 1975a; Thomas 1975b; Jacobson 1951). With the development of inbred strains of mice, many discoveries in the field of immunology, immunogenetics, and radiation oncology have taken place. Important early transplant studies by Van Bekkum and de Vries were summarized by E. Donnall Thomas and Rainer Storb (Thomas 1975a; Thomas 1975b). They discovered that: (1) the delivery of bone marrow intravenously was efficient in rescuing the immunoablated recipient animal; (2) donor bone marrow would cause a “secondary disease” or “runt disease” in mice from which the recipient animals would die unless they were genetically identical [This disease was later identified as GVHD]; (3) genetic factors dictated the severity of GVHD; and (4) the use of immunosuppressive agents (such as methotrexate) was able to ameliorate the GVHD reaction in allogeneic transplants, implicating the immune system as the culprit in GVHD (Thomas 1975a; Thomas 1975b).

Hematopoietic stem cell transplantation (HSCT) is most commonly used for the treatment of hematologic and lymphoid neoplasias and less commonly for non-neoplastic diseases. Mice are the premier animal model for researching novel therapies for the cure of many of these neoplastic and non-neoplastic diseases. Furthermore, mice are used extensively for the study of BMT-related complications such as GVHD. Acute GVHD and leukemic relapse remain the two major obstacles to successful outcomes after allogeneic bone marrow transplantation. We will concentrate on common mouse models that are used to understand the major factors governing graft versus host responses (GVHR) and its side effect, GVHD. These effects are closely intertwined with GVL effects.

Although HSCT is a lifesaving treatment for many patients, the side effects limit its success and wider application. Graft versus host disease (GVHD) is the most common complication and can affect up to 75% of patients. First described in 1962, GVHD was later classically characterized by Billingham as a syndrome in which a graft from an immunocompetent donor recognizes non-self antigens and attacks the immunocompromised cells of the allogeneic recipient (Shlomchik 2007). GVHD can present both acutely and chronically. Acute GVHD (aGVHD) is most often categorized as disease onset within 100 days of transplant, and is a rapidly progressive illness with a strong inflammatory component. In addition to the significant morbidity and mortality of aGVHD, it has also been found to be a powerful predictor of chronic GVHD risk (Copelan 2006), which displays more autoimmune and fibrotic features (Martin 2004). Chronic GVHD was categorized when the

disease developed 100 days post-BMT. Clearly this method of categorization of GVHD has had to be modified with the much-improved post-transplant pharmacological approaches where acute GVHD has been observed beyond 100 days. Acute and chronic GVHD is being divided nowadays based on their immunological profiles. While acute GVHD is a CD8 T cell driven, chronic GVHD has been dominated by the generation of allo-antibody and resembles more an antibody-mediated auto-immune condition.

ACUTE GVHD

The induction of acute GVHD is a stepwise process divided into an afferent and an efferent phase (Ferrara 2009). Multiple well-written reviews have been published (Copelan 2006; Shlomchik 2007; Duran-Struuck 2008a). The afferent phase is characterized by donor T cell activation which can be broken down into three steps. First, an inflammatory environment is propagated as a direct result of the pre-transplant conditioning protocol (Ferrara 2009). Next, MHC-peptide complexes are presented on the surface of host antigen presenting cells (APCs) and recognized by mature T cells through the T cell receptor (TCR). Once engaged with the TCR, host APCs produce co-stimulatory signals which activate the T cells. Activated T cells then produce further cytokines, such as IL-2, which act in an autocrine manner to induce clonal expansion. In the efferent phase, these activated T cells produce inflammatory cytokines, recruit additional effector cells, induce the expression of HLA proteins and focus the attack on target organs. This is a self-perpetuating disease state that is difficult to control. 15% of annual HSCT patients die from aGVHD, and this mortality rate can reach 50% for chronic GVHD (Copelan 2006; Ferrara 2009). For these reasons, it is imperative that we develop a better understanding of the mechanism of induction and the factors underlying the severity of disease.

Crucial insights into the pathophysiology of GVHD have been provided by both small and large animal models of GVHD. These insights have in turn, led to improved clinical outcomes of patients suffering from GVHD.

There are multiple approaches to mitigate GVHD. These combine the use of pharmacological and biologicals (Table 1). In general, all of these are aimed at targeting T cells but often impact more than one immunological cell subset rendering the animal (or patient) significantly immunosuppressed.

MURINE MODELS OF BONE MARROW TRANSPLANTATION AND ACUTE GVHD

Murine animal models have been crucial for the elucidation of immunobiology questions related to bone marrow transplantation. When compared to other species, mice have several advantages that have facilitated these advances. Mouse models are attractive because of their small mass, large litter size, short pregnancy period, the availability of diverse stocks and strains as well as the use of transgenic, knockout (KO) and knock-in (KI) mice have made them the most valuable and versatile experimental animal model for biomedical research. Additionally, mice are relatively inexpensive. Large populations of mice can be maintained in

facilities designed specifically for rodents. Several inbred strains are available and have been well characterized; inbred strains have allowed for large experiments where all individuals are genetically identical (as compared to outbred stocks). Knockout and transgenic technology has enabled the study of specific immunological mechanisms by providing a tool that keeps most genetic factors constant. Of all animals, the murine immune system is the best defined. In fact, the major histocompatibility factor (H2) system, was discovered in mice in the 1940's (Snell 1980). Besides man, mice have the highest number of available biological reagents. Some of these reagents include, but are not limited to, monoclonal antibodies, cytokines and growth factors.

Table 1. GVHD treatment/sparing strategies

Biologicals		CELLULAR TARGETS	EFFECT
a)Cells	Regulatory T cells (Tregs)	T cells, B cells and innate cells	Direct cell:cell contact immunosuppression/kill and cytokine mediated
	Mesenchymal stromal cells	T cells and innate cells	Cytokine mediated and through indirect increases of Tregs
	Chimeric antigen Receptors on T cells (CARs)	Tumor targets	Direct cytotoxicity and kill of tumors
b)Antibodies	Anti-thymocyte globulin (ATG)	T-cell	Apoptosis
	Anti-CD52	T cell & B cell	Apoptosis
	Anti-CD20 (Rituximab)	B-cell	Apoptosis
	Anti-CD2, CD3, CD5 monoclonal antibodies	T-cell	Apoptosis
	Infliximab (monoclonal antibody)	TNF- α	Anti-TNF
Non-pharmacological	Reduced intensity conditioning	Decreased pre-transplant organ damage	Decreased TNF- α , IL-1 and LPS translocation
	Extra-corporeal photopheresis	T-cell apoptosis	8-MOP T cell sensitization
Pharmacological	Glucocorticoids (1 st line)	Lymphocytes, monocytes	Anti-inflammatory and apoptosis
	Mycophenolate mofetil (MMF)	T-cell	Inhibition of monophosphate dehydrogenase
	Rapamycin (Sirolimus)	T-cell	Inhibits (G1 $\rightarrow$ S) phase transition
	Cyclosporine	T-cell	Calcineurin inhibitor through cyclophilin
	Tacrolimus	T-cell	Calcineurin inhibitor through FK506 binding protein
	Etanercept (Enbrel)	TNF- α	Soluble TNF- α receptor

Mouse models of GVHD can be separated into animals in which GVHD is directed to either MHC class I or class II, both, or isolated to multiple minor antigens (miHAs). Although multiple miHA mismatches are present across major MHC mismatches, their impact is usually limited relative to that induced by full MHC disparities (Reddy 2008). The GVHD that develops in response to a full (class I and II) MHC disparity is dependent on CD4 T cells and CD8 T cells. These systems result in an inflammatory "cytokine storm," capable of inducing GVHD in target tissues without the requirement for cognate T cell interaction

with MHC on tissue (Teshima 2002). In contrast to CD4-dependent GVHD, CD8 T cells induce GVHD primarily by using their cytolytic machinery, which requires the TCR to engage MHC on target tissue (Duran-Struuck 2008a). The induction of GVHD to multiple miHAs results in a process that involves either CD8 T cells, CD4 T cells, or both, depending on the strain combination (Table 2).

Table 2. H2 haplotypes of common used mouse strains

Strain	H-2 complex			
	MHC-I		MHC-II	
	K	D	A	E
<i>Common strains</i>

B10a	k	d	k	k

These mouse models have helped dissect and shape the complex immunopathology of GVHD. It is critical to understand that no single mouse model can be considered the most appropriate for clinical BMT, because clinical BMT recipients that are MHC matched with the donor also have multiple miHA disparities. In the laboratory, both MHC and miHA disparate systems can induce aspects of GVHD which are clinically relevant. These permit the isolation of immunological pathways for understanding the mechanisms of GVHD.

Radiation, as a form of myeloablation, is most commonly utilized in mice. Inbred mouse strains (including congenics) demonstrate variable sensitivity to radiation (Duran-Struuck 2008b). The higher the TBI dose, the more intense the inflammatory arm (cytokine storm) of GVHD will be. BMT models utilizing low TBI doses and high donor T cell doses result in GVHD dominated by later onset T cell-dependent pathology (Reddy 2008). Other forms of chemotherapy conditioning with cyclophosphamide, fludarabine, and busulfan can also be delivered in mouse systems, however, these are more commonly used in large animal studies.

Like many animal models, mice have limitations and major differences. First, mouse BMTs are usually supplemented with T cells from the spleen in order to induce GVHD. This is because BM itself, even across MHC barriers, does not cause GVHD. In larger species, such as humans and pigs, BM-derived T cells are sufficient for inducing GVHD (Duran-Struuck 2015; Duran-Struuck 2016; Duran-Struuck 2017). Currently, most of the BMTs in humans are performed with peripheral blood cells (PBCs) only. PBC transplants in mice are rarely used because of size limitations and blood volume limitations. Second, mouse pre and peri-transplant preparatory regimens do not follow the protocols used in humans, who are

gradually rendered immunosuppressed over a number of days. Mice are generally given a myeloablative irradiation dose 2–24 hours prior to the intravenous delivery of the bone marrow graft.

BMT and its applications in mice have been used in a plethora of research fields. Here we will concentrate on the use of these animal models for BMT biomedical research and immunobiology. More specifically, we discuss the use of BMT for the study of GVHD and for its anti-leukemia (GVL) effects, since leukemia relapse and GVHD, as mentioned before, remain the two major obstacles for successful BMT.

Many of the pivotal concepts in BMT have been elucidated by studying the donor:recipient combinations in mice. As described by Shlomchik (Shlomchik 2007), these can be divided into: (a) MHC identical, minor histocompatibility antigen (b) MHC disparate in different background strains (c) MHC disparate in identical background strains (d) the use of strains where single MHC-I or MHC-II alleles differ by a small number of peptides (e) Parent → F1 models.

These combinations have been very important in addressing the involvement of specific cell subsets causing GVHD. T cells have been identified to be important factors for the development of GVHD (Ferrara 1999). As an example, different transplant combinations have induced immune responses mediated by CD4⁺ T cells, CD8⁺ T cells, or a combination of both. It should be noted that besides effector T cells, other cell lines such as B cells (Rowe 2006), natural Killer cells (NKCs) (Sentman 1989), and T regulatory cells (Tregs) (Nguyen 2006) have been identified to have an impact in the development or protection of the GVH response. Therefore, the use of mouse models has aided in polarizing the immune system in an effort to dissect the involvement of each one of the multiple factors involved in GVHD. Such “clean” studies, most likely, would have not been able in larger, outbred species because of the genetic variability between animals.

In summary, mouse models, including KI and KO systems, and the use of phenotyping markers (monoclonal antibodies), availability of agonist/antagonists of chemokines, cytokines, co-stimulatory molecules, have proven to be crucial for the elucidation of BMT engraftment and GVHD pathophysiological processes. Clinical applications of many of the concepts discovered in mice have proven to be necessary in pre-clinical large animal models. In our case, we used the pig.

LARGE ANIMAL MODELS OF GVHD

1. Canine Models

Progress in experimental bone marrow transplantation in canines has provided for the translation of dog experimental findings to the clinic. The therapeutic application of marrow grafting in dog has been applied to a variety of human diseases. Dog models of total body irradiation, engraftment and graft-versus-host disease have been (and continue to be) used to address existing clinical problems of hematopoietic cell transplantation and GVHD. Domestic dogs with spontaneously occurring lymphomas and other cancers are used for cellular therapies (as an example, at the University of Pennsylvania (Panjwani 2016) novel chimeric antigen receptor (CARs) T cell approaches are being studied in domestic dogs). Clinical

parameters necessary for implementing safe autotransplant approaches in conjunction with high dose radiation and/or chemotherapy have been studied in dogs. Chemicals, radiation, antisera and monoclonal antibodies have been (and continue to be) developed in laboratory bred dogs as a model for human transplantation. Interestingly, the demand for enhanced clinical medical care in domestic dogs has pushed this model beyond experimental use. As a GVHD model, the refinement of approaches that suppress the immune system either nonspecifically using radio/chemo ablation, or directed to specific immune cells continues to be an area of research in which the dog continues to play a big part.

Much of the early work in large animals studying GVHD was at first performed in canines. The Seattle group led the way with early experiments demonstrating the importance of HLA matching in preventing GVHD after BMT. Crucial to these efforts was the development of a reproducible model of lethal acute GVHD in which dogs receiving between 8.5 – 9.2 Gy TBI and dog leukocyte antigens (DLA)-nonidentical unrelated marrow grafts without any immunosuppression died shortly after transplant due to effects of GVHD (Atkinson 1982). Using this model as a foundation, a major contribution to the understanding of GVHD by the Seattle group was studying the effects of different immune suppression regimens on GVHD. Many of these early immunosuppressants tested in the canine model are the same ones used today in clinical BMT, including cyclosporine A (CyA), mycophenolate mofetil (MMF), and methotrexate (MTX) (Table 1).

In the early 1980s, E. Donald Thomas and colleagues reported GVHD-free survival in 12/13 animals receiving treatment with methotrexate following supralethal levels of TBI and hematopoietic grafts from DLA matched littermates. This was compared to animals who did not receive methotrexate, in which 16/28 animals developed and died of GVHD. Thomas went on to examine the effect of combination Cyclosporin A and methotrexate (MTX) as a prophylaxis against GVHD (Deeg 1984). They showed that combination MTX and CyA was superior to MTX alone in prophylaxing against GVHD in recipients conditioned with 9 Gy of TBI and receiving DLA-haploidentical transplants (Deeg 1984). This initial work sparked controlled clinical trials assessing the efficacy of combination MTX and CyA for GVHD prophylaxis. Yu et al. demonstrated the synergistic effect of mycophenolate mofetil (MMF) and cyclosporine for the prevention of GVHD in this model (Yu 1998). Dogs receiving either MMF or CyA alone after transplant had increased survival compared to control dogs not receiving any immunosuppression, but all dogs eventually died secondary to GVHD. Groups of animals receiving combination MMF and CyA had greater than 50% survival. Kuhr et al. tested RDP58, a novel anti-inflammatory peptide derived from the HLA class I heavy chain, in prophylaxing against GVHD in this model (Kuhr 2006). Unfortunately, in five dogs that engrafted after transplant, all five developed acute GVHD and were euthanized at 20 days after HCT, not significantly prolonging survival compared to control animals. Similarly, FTY720, also known as Fingolimod, which is the first oral disease modifying drug for the treatment of multiple sclerosis, did not significantly increase survival after the development of GVHD in this model (Lee 2003). Denileukin diftitox, also known as Ontak, an anti-IL2 receptor immunotoxin was unable to mitigate GVHD or increase survival (Mielcarek 2006). The addition of glucocorticoids to tacrolimus or tacrolimus/MTX combination did not show a synergistic effect with respect to the prevention of GVHD or increasing survival compared to tacrolimus or tacrolimus/MTX combination alone (Yu 1997).

More recently, Zorn et al. showed the reduced incidence of GVHD in a canine model of DLA-homozygous donor and DLA-heterozygous recipient transplant using CD6-depleted

bone marrow (Zorn 2009). In a control group of 7 canines treated with 10 Gy TBI and receiving unmanipulated bone marrow, all animals died of GVHD within 1 month of transplantation. Animals treated with the same preparatory regimen but receiving CD6-depleted bone marrow using a mouse-anti-human antibody which cross reacts with the canine CD6 antigen, had a significantly reduced incidence of GVHD without jeopardizing the engraftment.

2. Primate Models

Non-human primates (NHP) have been used in transplantation for several decades. Leukaphoresis can be performed in NHPs (Pathiraja 2013) as an alternative to BMT. Not until relatively recently have been MHC-characterized colonies made available for experimental purposes (to mimic allogeneic BMT has been performed like in mice or humans). Two NHP models, one in *cynomolgus macaques* (*cynos*) and one in *rhesus macaques* (*rhesus*) have genotyped and characterized their MHC to better design transplant studies. A population of *cynos* has been naturally isolated on the small island of Mauritius. The Mauritian Islands have been naturally separated from the main land Asia for hundreds of thousands of years. Over five hundred years ago Asian *cynos* were brought by settlers to the islands from Asia as few founder animals. This geographic isolation has allowed for some natural inbreeding to occur, narrowing their genetic MHC diversity to 6 different haplotypes (PHS 1996; O'Connor 2007). This makes the Mauritius cyno a particularly attractive model for immunological studies. No studies focusing in GVHD have yet been reported using these animals, but have been recently made available commercially and will be an invaluable tool for studies of GVHD biology. There is a recent study which extensively describes the leukocyte populations within the lymphohematopoietic organs (bone marrow, peripheral blood, thymus, lymph nodes and spleen) from these animals providing a platform upon which to build from (Duran-Struuck 2017; Zitsman 2016). No other study exists to date that describes in such careful detail all these cell subsets in GVHD target organs. It is a matter of time that these are further utilized for studies of GVHD.

Under a closely managed breeding program at Yerkes National Primate Research Center and the direction of Kean and colleagues, the NHP GVHD model has been established. This new model is currently being used as a valuable tool to pre-clinically screen novel checkpoint blockade immunotherapies (Kaliyaperumal 2014; Miller 2010). As an example, studies from Miller et al. reported that 100% of animals conditioned with 8 – Gy TBI on day 0 developed rapid-onset of severe GVHD involving the skin, GI system, and liver (Miller 2010). Two of three animals receiving leukapheresis-derived grafts succumbed within 7 days, and 1 animal who received a BM-derived graft succumbed at day 22. Clinical disease correlated closely with CD8⁺-predominant lymphocyte expansion and activation. In these animals, expanding CD4⁺ and CD8⁺ lymphocytes expressed a memory phenotype as indicated by CD95⁺ cells. Interestingly, the majority of expanding CD4⁺ cells expressed a central memory phenotype (CD28⁺/CD95⁺) compared to expanding CD8⁺ cells which predominantly expressed an effector memory phenotype (CD28⁻/CD95⁺). Regardless, both expanding CD4⁺ and CD8⁺ lymphocytes significantly upregulated expression of Ki67, an intra-nuclear marker of proliferation, and downregulated expression of BCL-2, an antiapoptotic protein. Furthermore, untreated animals developing GVHD accumulated high levels of IL-1RA, IL-18, IFN γ , and

CCL4. Alternatively, five animals treated with 8 Gy TBI in addition to costimulation blockade (CTLA4Ig and anti-CD40L monoclonal antibody) and sirolimus were initially protected from the severe GVHD observed in the untreated recipients and showed 100% survival at day 30, compared with 0% 30 day survival among the untreated animals. T cell activation in treated animals was significantly reduced, and treated animals retained a cohort of naïve CD4 and CD8 T cells (CD95⁻) despite alloantigen exposure that was essentially absent in untreated animals. Despite early protection from GVHD, all treated animals did eventually succumb to GVHD. This was hypothesized to be due to a subset of CD8⁺ T cells (CD28/CD95⁺) exhibiting breakthrough immune activation despite treatment with costimulation blockade and sirolimus. This subset of CD8⁺ T cells exhibited an activated phenotype as evidenced by Ki67 upregulation and Bcl-2 downregulation.

3. Swine Models

Studies and descriptions of GVHD in swine have mostly been performed by Sachs and colleagues. The pig is arguably one of the best models for the study GVHD, in particular skin GVHD (Duran-Struuck 2016). To date, the most extensive swine studies of HSCT and GVHD come from the Massachusetts General Hospital (MGH). Over a period of 40 years, David Sachs has developed a herd of partially inbred, MHC-defined miniature swine that have allowed for the study of different clinical HSCT scenarios including minor antigen mismatch, haploidentical match, and full MHC mismatch (Cina 2006). The development of acute GVHD in swine involves the same organ systems as in humans, including skin, liver, gastrointestinal system, and bone marrow (Duran-Struuck 2015). Skin GVHD is the earliest and most common manifestation in swine. Lesions usually involve the neck, back and abdomen of animals, often becoming confluent and ulcerative in nature. Histologically, a differentiating feature of swine GVHD is a denser infiltrate of neutrophils into the skin. This is seen in addition to the classic lymphocytic infiltrate seen in human. An extensive review of swine as a model for GVHD has recently been published (Duran-Struuck 2015).

Early studies from MGH showed that in a haploidentical model (parent to F1), 100% of recipients (n = 18) irradiated with 900 cGy of TBI successfully engrafted after allogeneic BMT. All but one recipient developed varying intensities of skin GVHD, which directly correlated with the degree of T cell depletion in the infused marrow. Similarly to humans, attempts at preventing GVHD by depleting the graft of T cells led to graft failure (Pennington 1988; Popitz-Bergez 1988; Sakamoto 1988).

Table 3. Major histocompatibility complexes in mice, pigs and men

Species	MHC-I	MHC-II
Mouse	H2-K, D, L	H2- A, E, O
Human	HLA- A, B, C	HLA- DR, DQ, DP

In mice, the administration of IL-2 post BMT between HLA-mismatched recipient/donor pairs reduces the incidence of GHVD. The effect of high dose IL-2 therapy on GHVD in swine was studied in a series of single haplotype mismatch and full haplotype mismatch transplants (Kozlowski 2000). In fully mismatched bone marrow transplants, high dose IL-2

therapy had no effect on the development of GVHD, and all swine eventually succumb to severe GVHD. However, in the context of single haplotype (class II) mismatched BMT, high dose IL-2 significantly reduced the incidence and severity of GVHD, which translated into increased survival.

Over time, the MGH group has developed a model of haploidentical hematopoietic cell transplantation using a novel reduced intensity conditioning regimen consisting of low dose total body irradiation, T cell depletion using a CD3 immunotoxin, and a short course of cyclosporine. This regimen results in stable multilineage chimerism without significant GVHD, and can induce immunological tolerance to solid organ grafts including kidney, lung, and vascularized composite allografts (Cina 2006; Hettiaratchy 2004).

GVHD AFTER SOLID ORGAN TRANSPLANTATION

The first description of GVHD after solid organ transplantation (SOT) in the literature was by Starzl et al. in 1984, who described GVHD in a patient after undergoing a combined pancreas and splenic transplant (Starzl 1984). Since then, there have been a number of case series retrospectively analyzing GVHD after SOT, specifically liver and small bowel allografts. However, due to the relatively rare incidence of GVHD after SOT, prospective studies of GVHD in humans are impractical. To date, no dedicated large animal model of acute GVHD after SOT exists, most likely related to its rare clinical incidence. Several rat models of GVHD after liver transplantation exist, and we will review those here.

1. Liver

1.1. Experimental

Xue et al. established a reproducible model of acute GVHD after liver transplantation and donor splenocyte infusion in Lewis rats. In this model, the level of chimerism after liver transplantation was shown to correlate with the development of acute GVHD (Xue 2009). Another subsequent study by the same group assessed the effect of tacrolimus vs. rapamycin on GVHD in this model (Xu 2010). They found that rapamycin significantly increased survival compared to tacrolimus, and this survival was associated with higher percentages of CD4⁺CD25⁺FoxP3⁺ T regulatory cells in the circulation and tissues. Finally, the infusion of either donor or recipient derived mesenchymal stem cells (MSCs) prior to the development of aGVHD symptoms (days 0–6) led to the abrogation of typical aGVHD symptoms seen in this model and led to significantly increased survival (Xia 2012). Interestingly, MSCs infused between days 8–14, after the typical symptoms of aGVHD started, had no effect on GVHD or survival. The group hypothesized that the mechanism of MSC protection against aGVHD was via the induction of Tregs, as MSC-infused rats had higher amounts of Tregs in the blood and intestines.

Another recent model of aGVHD after liver transplantation in rats involved preconditioning recipients with sublethal irradiation plus treatment with anti-CD8a mAB to deplete radioresistant NK cells (Yu 2016). Subsequent transplantation of liver allografts alone without a cellular graft consistently resulted in lethal aGVHD. Interestingly, in an attempt to

abrogate aGVHD in this model, donor livers were perfused *ex vivo* with a media containing a TCRAb mAB, and then transplanted using the same preparatory regimen. *Ex vivo* T cell depletion of liver grafts prevented aGVHD without any accompanying effect on graft function. This strategy may be a viable clinical option in high risk donor and recipient pairs undergoing liver transplantation.

1.2. Clinical

It has been almost 30 years since a case of acute GVHD after orthotopic liver transplant (OLT) was first described in the literature by Burdick et al. (Burdick 1988). Since that sentinel report in 1988, there have been numerous case reports describing GVHD after OLT, as well as several large series reporting on incidence and outcomes (Taylor 2004a; Taylor 2004b; Smith 2003). The three prerequisites that Billingham set forth in his initial description of GVHD after *bone marrow transplant* hold true for the development of GVHD after solid organ transplant. It is estimated that a donor liver graft retains between 1×10^9 and 1×10^{10} passenger leukocytes within its parenchyma and portal tracts even after aggressive flushing with cold preservative solution⁵³. This is equivalent or greater to the number of donor lymphocytes transplanted during an HSCT. In the first few weeks following OLT, these donor leukocytes can often be detected in the recipient blood.

As expected, compared to cell transplantation, GVHD after OLT has a much lower incidence, estimated at 1–1.5% (Akbulut 2012). Despite its low incidence, GVHD after OLT carries a dismal prognosis, with a mortality of 85–90% (Smith 2003). GVHD after OLT manifests anywhere between 1–8 weeks following transplantation and produces a similar clinical picture of GVHD after HSCT with symptoms including rash, fevers, diarrhea, and pancytopenia. Marked neutropenia and thrombocytopenia can often precipitate life-threatening infection or hemorrhage. One notable difference is the absence of hepatic and biliary dysfunction as GVHD is restricted to host derived tissues.

Several retrospective analyses have identified risk factors for the development of GVHD after OLT. The most important risk factor appears to be the sharing of HLA antigens between recipient and donor, specifically the use of an HLA homozygous donor. This results in complete one way HLA antigen match in the GVH direction, predisposing to GVHD. Kamei et al. analyzed 8 cases of fatal GVHD after OLT in Japan, and found that all eight cases had one-way HLA matching in the GVH direction in the three loci, HLA-A, HLA-B, and HLA-DR (Kamei 2006). The authors concluded that the risk of fatal GVHD after OLT was likely associated with the number of loci (with the one-way HLA matching) and those with mismatching at all 3 loci (HLA-A, -B, -DR) were at highest risk. In another retrospective series of 12 patients who developed GVHD after OLT by Smith et al. identified several risk factors including close matching at HLA antigens, recipient age >65, and age difference >40 years between donor and recipient (Smith 2003).

Due to the rare incidence of GVHD after OLT and its generally vague presenting symptoms of fever, rash, and diarrhea, the diagnosis of GVHD is not always made immediately. Often times, drug reactions and infectious processes, such as cytomegalovirus (CMV) are investigated first as these are much more common. The strongest supportive evidence for a diagnosis of GVHD, short of a biopsy, is a large number of circulating donor derived T cells in the peripheral blood, referred to as chimerism. These donor cells may be identified by flow cytometry, serologic typing, or PCR-based analysis. In the case of sex

differences between donor and recipient, fluorescence in situ hybridization (FISH) analysis can distinguish donor and recipient lymphocytes (Kanehira 2009). It is important to remember that the majority of liver transplant recipients will have detectable donor-derived lymphocytes in the peripheral blood for the first two weeks, but usually taper off by that time (Schlitt 1993). Therefore, the presence of large numbers of donor-derived lymphocytes several weeks after transplant in the setting of fever, rash, diarrhea, etc. should prompt immediate investigation.

Due to the rare incidence of GVHD after OLT and variable patient scenarios, a standardized and proven treatment modality is lacking. Instead, the literature contains various case reports reporting on different treatment strategies, often in a small cohort of patients. Nevertheless, the majority of these reports revolve around several different therapeutic approaches including the use of corticosteroids, increasing/reducing the dose of immunosuppression, and the use of antibody preparations such as antithymocyte globulin (ATG) or OKT3 to eliminate donor lymphocytes. Each has had variable success, and as such, not one agreed regimen yet exists.

The use of corticosteroids for the treatment of GVHD is based on the HSCT experience, in which steroids are the mainstay of treatment and have largely been successful. Although the exact mechanism by which corticosteroids dampen the GVH reaction is not completely understood, it is thought to be a combination of their lymphocytic and anti-inflammatory properties. The use of corticosteroids appears to be the first line approach by many clinicians based on a review of the literature. In the most comprehensive literature review to date, Akbulut et al. reviewed 87 cases of GVHD after OLT (Akbulut 2012). They reported the use of corticosteroids in 61 of 87. Of those 61 patients, 43 died. In the majority of patients who had a suboptimal response to corticosteroids, a variety of other agents were added to attempt to control GVHD. Of these agents, ATG and basiliximab were the most commonly used adjuncts. Regardless, mortality rates did not significantly differ based on the treatment regimen used and remained high.

Another approach is to reduce the level of immunosuppression, thereby allowing the host immune system to reconstitute and mount an immune response to eliminate the donor lymphocytes mediating the GVHD response. The theoretical downside to this approach is the risk of liver rejection in the absence of host immunosuppression. A prospective series of three patients by Chinnakotla et al. suggested that later onset of GVHD (>8 weeks) and lower levels of donor chimerism (<20%) may be predictive factors of favorable GVHD response to withdrawal of immunosuppression (Chinnakotla 2007). In that report, two patients with late onset GVHD (10 weeks, 18 weeks) and low levels of peripheral blood donor chimerism (7%, 11%) underwent withdrawal of immunosuppression and experienced reduction of donor chimerism levels and rapid resolution of symptoms. Both patients did experience mild cases of acute cellular rejection in response to immunosuppression withdrawal, but these were successfully treated with a short course of steroids. A third patient who developed symptoms of GVHD at 2 weeks and had 26.5% donor chimerism in the peripheral blood did not immediately respond to withdrawal of immunosuppression and had worsening of clinical symptoms, eventually dying of uncontrolled sepsis on day 63.

2. Intestine

2.1. Experimental

The first published report of intestinal transplantation came in 1959 by Richard Lillehei, who reported an experimental model for isolated intestinal transplantation in canines (Lillehei 1959). With the introduction of cyclosporine and later tacrolimus, intestinal transplantation has now become a viable clinical option for patients with short bowel syndrome (SBS) who are total parenteral nutrition dependent. Early studies by Lillehei demonstrated that some dogs who died early after intestinal transplantation had relatively normal graft histology, but did have enlarged mesenteric lymph nodes, suggesting that GVHD could develop after intestinal transplantation (Lillehei 1963). Later, a heterotopic small bowel transplant model was developed in rats by Monchik et al., in which GVHD reproducibly led to recipient death within 12–20 days (Monchik 1971). That model was used as a foundation for further studies which showed that immunocompetent T cells in the intestinal grafts were necessary for the induction of GVHD (Kirkman 1984). Donor T cells adoptively transferred from recipient spleens of intestinal transplants were able to induce a graft vs. host reaction in animals syngeneic to the recipient (Pomposelli 1985). Deltz et al. also showed that the extent of GVHD correlated closely with the amount of lymphoid tissue contained within the donor intestinal graft (Deltz 1981). Interestingly Shaffer et al. attempted to abrogate the development of GVHD in this model and were able to demonstrate the effectiveness of pretreatment of donor rats with antilymphocyte serum (ALS) prior to small bowel transplantation (SBT) (Shaffer 1988). ALS prior to SBT prevented GVHD in recipient rats without adversely affecting graft function in both heterotopic and orthotopic allograft models.

There are few large animal models of SBT, likely due to the cost and technical difficulty of the operation. Hale et al. developed a model of heterotopic small bowel allotransplantation in non-human primates (rhesus macaque and baboons) that led to long-term graft survival using an immunosuppressive regimen of Cyclosporine 40 mg/kg/day, Solu-Medrol 2 mg/kg/day, and Azathioprine 5 mg/kg/day (Hale 1991). Graft survival using this immunosuppressive regimen was 75.3 days, and three long-term survivors were euthanized for presumed sepsis with viable grafts. Importantly, there was no incidence of GVHD.

Miura et al. compared the efficacy of heterotopic vs. orthotopic small bowel transplantation in MHC inbred miniature swine and found that orthotopic SBT was superior (Miura 2016). All heterotopic grafts underwent ischemic changes soon after transplantation, presumably due to a compartment-syndrome type process in the limited abdominal space. However, when the native small bowel was removed and orthotopic small bowel allografts were transplanted into swine, all grafts were viable on autopsy and showed no signs of ischemia. Furthermore, compared to recipients of orthotopic small bowel allografts, those swine receiving heterotopic allografts had higher elevation of serum inflammatory cytokines and had a significantly faster progression to lethal metabolic acidosis. In both heterotopic and orthotopic SBT, there was no incidence of GVHD.

2.2. Clinical

Clinically, GVHD following small bowel transplant (SBT) is more common than after other solid organ transplants due to the significant amount of lymphoid tissue contained within the small bowel, particularly the ileum. Several case series reporting on GVHD after

SBT have described the incidence between 5–10% (Andres 2010; Mazariegos 2004; Wu 2011). However, because SBT is a much more recent endeavor compared to liver transplantation, there is less published literature regarding GVHD after SBT. Therefore, we will focus on three large retrospective analyses describing the incidence of GVHD after intestinal transplantation (ITx).

In 2004, Mazariegos et al. reviewed 250 adult and pediatric patients receiving ITx between 1990 and 2003 at a single transplant center (Mazariegos 2004). There was a mix of isolated small bowel transplants (44.8%), combined liver and small bowel transplants (36.8%), multivisceral transplants (12.8%), and modified multivisceral transplants without liver (5.6%). Immunosuppression regimens were also quite variable and evolved overtime from a baseline tacrolimus and steroid therapy to include cyclophosphamide, daclizumab, or antibody preconditioning with either thymoglobulin or Campath.

Of the 250 patients included in the study, GVHD was clinically suspected in 23 (9.2%) (6 adults, 17 children) patients based on clinical presentation including skin rash, diarrhea, lymphadenopathy, liver dysfunction, or oral mucosal ulceration. The median onset of GVHD was 1.2 months, which is consistent with acute GVHD. Risk factors for the development of GVHD included multivisceral transplantation and crossmatch negative patients. Multivisceral transplant recipients were twice as likely to develop GVHD as those receiving isolated small bowel transplants, most likely related to the increased lymphoid tissues in multivisceral grafts. Crossmatch negative patients were also more likely to develop GVHD as would be hypothesized, as recipient neutralizing antibodies would have a deleterious effect on donor graft T cells.

Of the 14 histopathological confirmed cases of GVHD, seven patients had increased donor-cell chimerism supportive of the GVHD diagnosis. Donor cell chimerism in those 7 patients was a median of 7.9%, and ranged from 0–35.9%. The majority of confirmed cases of GVHD were mild (Grade I-II) and confined to the skin, although several included the GI tract. There was only 1 case of chronic GVHD. Fortunately, of the 23 cases of suspected GVHD, there were only 2 deaths and neither directly attributed to GVHD. GVHD was resolved in the other 21 patients. 4 patients resolved spontaneously without intervention while the others resolved after either steroid boluses or a methylprednisolone taper.

In 2010, Andres et al. reviewed 46 pediatric patients who underwent SBT between 1999 and 2009 (Andres 2010). Of the 46 patients, 5 (10.8%) developed GVHD as determined by clinical diagnosis. Similarly to the previous study, those patients receiving multivisceral transplants were more likely to develop GVHD as two of the five patients received combined liver-intestinal transplants and three patients underwent multivisceral transplants. There was no GVHD observed after isolated SBT. The median time to GVHD was 47 days (16–333 days). All five GVHD patients had skin manifestation, two had concomitant GI symptoms and three interestingly had respiratory symptoms. Histopathological diagnosis of GVHD was made in four of the five patients, and donor chimerism levels were supportive of the diagnosis in two patients. In contrast to the study by Mazariegos et al, the majority of GVHD observed in this study was severe (Grade III-IV). All five patients were initially treated with high dose steroids (HDS), and four of the five patients had a partial response to therapy defined as a decrease in stage of GVHD. Of the five patients who developed GVHD in this study, three died due to complications of GVHD within four months of diagnosis, a stark contrast to previous studies.

In 2011, Wu et al. reviewed 241 adult and pediatric patients who underwent intestinal transplantation during a 13 year time span between 1994 and 2007 (Wu 2011). The incidence of GVHD was 9.1% (22/241) as determined by clinical diagnosis and confirmed by histopathological evidence. Of the 10 patients with available flow cytometric analysis, four had confirmed macrochimerism ($>1\%$) and the remaining six had detectable microchimerism ($<1\%$). The median onset was twice that of the previous study by Mazariegos et al. (2.5 months vs. 1.2 months). Risk factors associated with the development of GVHD included age, diagnosis, type of graft, and the presence of splenectomy. Children less than 5 years of age were more likely to develop GVHD than were adults (13.2% vs. 4.7%). Interestingly, patients requiring transplant for intestinal atresia were more likely to develop GVHD than those with other diagnoses including gastroschisis, necrotizing enterocolitis, or Hirschsprung's disease (22.2% vs. 2.6%). Consistent with previous studies, recipients of multivisceral transplants were at higher risk of GVHD than those recipients of isolated SBT (12.4% vs. 4.6%). Finally, the addition of recipient splenectomy was also associated with a higher rate of GVHD (13.6 vs. 6.8%). Crossmatch status was not associated with GVHD in this study. Of the 22 cases of GVHD, all involved the skin and all but three were considered mild (grade I-II). Despite the majority of GVHD cases being grade I-II, 17/22 patients died in follow-up, with infection being the most common cause of mortality. The authors concluded that treatment with corticosteroids and increased immunosuppression was inadequate to control GVHD in this series.

Although younger age appears to be associated with a higher chance of developing GVHD and a higher GVHD-associated mortality, it is unclear in these studies whether age is an independent risk factor or whether this association is affected by other variables. In Wu et al. children < 5 were more likely to receive a multivisceral transplant which may have been a factor. Alternatively, one hypothesis to the association between younger age and GVHD could be the underdeveloped immune system of children and their inability to mount an immune response. Similarly, the inability to mount an immune response could be the mechanism by which recipients of recipient splenectomy seem to be more prone to GVHD as in the study by Wu et al.

The most glaring difference between the results of Mazariegos et al. and Wu et al. were the responses to treatment after development of GVHD as well as the GVHD-associated mortality. The vast majority of patients reviewed by Mazariegos et al. that were suspected of having GVHD ($n=23$), either resolved spontaneously or responded promptly to corticosteroids and adjustment of tacrolimus doses. On the other hand, patients treated with corticosteroids and increased immunosuppression in the series by Wu et al. did not respond to conventional therapy and 77% of patients died of GVHD-related complications according to the authors.

SPLEEN

Small and large animal models of spleen transplantation are uncommon due to the fact that clinical splenic transplantation is rare. The spleen is not a vital organ for survival, and thus justifying long term immunosuppression for splenic transplantation is difficult. However, there have been several studies in large animals assessing the use of splenic transplantation to

induce mixed hematopoietic chimerism and immunological tolerance. The rationale is that the spleen is a relatively rich source of hematopoietic progenitor cells. Dor et al. showed that spleen allografts can be accepted across full MHC mismatch barriers in miniature swine (Dor 2005). The acceptance of splenic allografts and continued viability was associated with multilineage chimerism in thymus, bone marrow and blood. Importantly, this multilineage chimerism was associated with donor-specific hyporesponsiveness and did not cause GVHD. Interestingly, two swine that were tolerant of splenic grafts were then transplanted with donor-MHC matched kidney allografts without immunosuppression which were both accepted. The authors concluded that splenic transplantation in miniature swine could result in hematopoietic cell engraftment in the absence of GVHD.

HOST-VERSUS-GRAFT (HVG) RESPONSES

Very few studies have investigated the causality of host-versus-graft responses after BMT. In general, graft loss has always been considered an unwelcomed outcome of BMT, especially when the anti-leukemia graft-versus-host responses sought were not harnessed. Host-versus-graft responses are known as rejection (in solid organ transplantation) or marrow failure/loss (in BMT patients). Little is known about the immunological processes involved in loss of donor bone marrow. The use of reduced intensity conditioning (RIC) regimens in BMT has facilitated the transplantation of patients who previously would have not been considered suitable candidates due to the toxicity of the myeloablative preparatory regimens (Li 2012). Although the risk of complications due to conditioning is decreased with non-myeloablative conditioning, the risk of graft loss is increased. Graft loss can be caused by several factors; i) rejection, ii) the inability of the stem cells (SCs) to engraft due to the lack of “space” (Salomon 1990) or iii) poor donor graft quality (Zeng 1997). These causes may lead to different immunological responses. Rejection of the donor graft implies an active immunological process whereby donor cells sensitize the host (through cellular and/or humoral mechanisms). Conversely, if the loss of donor cells is not immunological, but due to a deficiency in stem cell “fitness” or stem cell quality, there may not be immunological consequences (e.g., sensitization). Some factors related to graft loss include donor/recipient MHC mis/match, the degree of host myeloablation, the level of immunosuppression post-HCT, the degree of host immune competence related to immediate preparatory regimens, the level of T cell depletion of the donor graft and pre-sensitization to donor antigens as is seen in aplastic anemia patients. Clinical studies assessing immune responses of patients following graft loss and after re-exposure of donor antigen have not been extensively investigated. A recent study investigated the immunological responses after graft loss in the MGH MHC defined miniature swine (Duran-Struuck 2012). In this study, recipients underwent reduced intensity conditioning and received cytokine mobilized peripheral blood mononuclear cells (PBMCs) which were haplo-mismatched at both MHC I and II. The RIC regimen consisted of CD3-immunotoxin, 100cGy of TBI and 45 days of cyclosporine A. Cellular and humoral anti-donor responses were studied before and after re-exposure to donor antigen and anti-donor (HVG) immune responses among transplanted and naïve animals exposed to donor antigen were compared. The data this study presented highlighted two important findings. First, peri-transplant conditioning could modify how the immune system responded to a graft

and that not all graft rejection was the same. Second, absence of *in vitro* evidence of sensitization by the means utilized (MLRs and antibody binding) did not correlate with absence of a sensitized response leading to the loss of the donor graft. Animals that lost their HCT graft following conditioning regained normal cellular proliferative and cytotoxic allo-responses to donors. These responses were similar in quality to a naïve animal and without any detectable anti-donor antibody responses. Interestingly and to the authors' surprise, whereas animals that lost chimerism might have been expected to have immune responses to donor antigen comparable to naïve animals, this was incorrect. Only after a second donor antigen exposure (without immunosuppression and in the form of a donor leukocyte infusion) in animals which lost chimerism, eventually induced a sensitized cellular immune response that differed from naïve animals. The studies suggested that the initial exposure to donor cells induced an immune response that may have contributed to graft loss but were not detectable with the immunological tools commonly used.

Immunologically, HCT recipients which presumably rejected their grafts, had a much higher host CD8⁺/CD4⁺ Tc ratio when measured by CFSE assays. Sensitized animals at a cellular level had very low CD4⁺ T cell proliferation. It was postulated that lack of antibody production in animals that rejected their graft was that CD8⁺ T cell responses may have overwhelmed the ability of CD4⁺T cells to provide sufficient B cell help (also known as immune deviation). Similar to the findings reported in the swine studies, immunological responses with a dominant CD8⁺ T cell population have been observed in patients that rejected their grafts (Kraus 2003).

In conclusion, and of clinical importance, a remarkable finding was the observation that allo-antibodies were never induced after graft loss or after leukocyte infusions. This does have important clinical implications since allo-antibodies are generally tested in the clinic to assess for sensitization (Gandini 2000). Hence, the data supporting allo-antibodies following graft loss may not be a reliable indicator for lack of sensitization and re-transplantation decisions based on their presence may be misleading. More studies are needed to provide further insight into the immunological responses after graft loss which may serve as a guide for modifications of preparatory regimens when subsequent re-transplantation of immune-sensitized hosts is considered.

CONCLUSION

We hope that this chapter provides insight of the strengths and weaknesses of animal models to study HVG and GVH responses and disease. There is no one best animal model. They all have their advantages and disadvantages. Clearly, large animal models (dog, pig, NHPs) approximate the clinical scenario with more fidelity than rodents do for the reasons discussed. The most important factor for the researcher will remain to identify the pre-clinical model that can best answer the experimental question. Often, more than one model may be necessary prior to translation to the bedside and begin clinical trials.

ABSTRACT

Given the genetic and epigenetic diversity of prostate tumors and their variable response to chemotherapy, therapeutic strategies against prostate cancer have experienced a framework shift from broad cytotoxic drugs to a more personalized level of medicine. This personalized approach not only results in superior medical care by improving effectiveness while diminishing toxicities, but it also directly impacts health economics and patient quality of life. In this scope, we present a novel model that allows empirical testing of therapeutic agents on *ex vivo* patient-derived tissues, cultured in a non-perfused microfluidic device. The proposed model relies on the micro-dissection of tumor biopsies and samples obtained through surgical resection of the prostate (radical prostatectomy or transurethral resection of the prostate) to produce micro-dissected tissue (MDT) samples, which are trapped in a microfluidic device and exposed to various combinations of drugs. Confocal microscopy and flow cytometry analysis are used to determine the viability of the drug-treated MDTs. These analytical methods are a promising way to determine therapeutic response or resistance and to help identify the optimal treatment plan for an individual patient in less than two weeks after tissue procurement. The presented model is simple to operate, cost effective, offers high-throughput potential through multiplexing,

and is clinically relevant to predict *in vivo* therapeutic response, thus making it a new tool with the potential to significantly improve the current treatment of prostate cancer.

INTRODUCTION

Despite the impressive stride forward in early diagnostics, prostate cancer remains the second leading cause of death by cancer in western countries. Given the genetic and epigenetic diversity of prostate tumors and their variable response to different agents, therapeutic treatment plan efficacy has become a challenge. Recently, therapeutic strategies against prostate cancer have experienced a framework shift from broad cytotoxic drugs to a more personalized level of medicine. This personalized approach not only results in superior medical care by enhancing effectiveness while minimizing drug-induced toxicities, but it also directly impacts health economics and potentially improve patient quality of life. To attain this goal, much effort has focused on predictive biomarkers that provide a statistical probability of response, however this approach has proven to be unpredictable and not always straightforward (Ginsburg 2001).

In this context, direct testing of therapeutic agents on the biopsied tumor mass, or on cell cultures derived from tumor tissues, has been proposed as a viable complementary method to predict patient response. So far, preclinical models used to address therapeutic efficacy and specificity have largely relied on monolayer (2D) cultures, either of cell lines or tumor explants. These often provide an imperfect measure of what is observed in xenografts or patients, largely because they do not take into account the tumor heterogeneity and the complexity of the tumor microenvironment (Justice 2009). Considering the limited amount of tissue available from biopsies and the long assay time to execute multiplexed drug resistance tests, the direct testing of treatment on biopsied tumor mass has not been feasible until recently.

In this chapter, we present a new model that relies on the application of microfluidic technologies coupled to micro-dissected tissue (MDT)-based sampling to assess the chemosensitivity profile of tumor tissues in a patient-specific manner. We first review the history and the advantages of microfluidics for drug screening applications in oncology. We then describe the design and fabrication of the microfluidic platform along with the methodology to produce the MDT samples and trap them into the microfluidic device for further culturing and maintenance. Finally, the MDTs can be treated with various therapeutic agents on-chip to allow confocal microscopy and flow cytometry analysis of MDT response to treatment.

EVOLUTIONARY HISTORY OF MICROFLUIDIC TECHNOLOGY

First introduced in 1990 in the seminal work of Manz et al., the concept of lab-on-a-chip (LOC) today has deeply influenced modern analytical chemistry and biology (Manz 1990). The idea behind LOC technologies is to miniaturize and integrate all the necessary steps for a particular assay in a low-cost and portable format, with fast analysis time and digital-like capabilities for efficient processing of biological samples. These LOC systems offer multiple benefits over their macroscale counterparts, including improved throughput and automation, which will be further detailed in this chapter. The history of LOCs is closely related to microfluidics where the science and technologies involve controlling small volumes of fluid at the sub-millimeter scale (Whitesides 2006). Some of the earliest applications integrating the concept of microfluidics and LOCs were used for analytical chemistry techniques: gas-phase chromatography (de Mello 2002; Terry 1979), high-pressure liquid chromatography (de Mello 2002; Manz 1990) and capillary electrophoresis (Kim 1996; Mathies 1992; Woolley 1994). Since then, a great number of biological applications ranging from genomics to cellular assays have been miniaturized and integrated into LOC devices. For instance, in fundamental research, LOC devices, which reproduce organ functionality, have been developed to study human physiology in an organ-specific context (Huh 2011). Often named “organs-on-chips,” various new *in vitro* models have been reported to study organ-specific functions of brain (Park 2009), liver (Kane 2006; Lee 2007), kidney (Jang 2010), gut (Kimura 2008), breast (Song 2009), and bone (You 2008). In a clinical context, LOCs have been used to provide a high-throughput platform to manipulate and probe tissue samples for drug screening (Astolfi 2016; Pak 2015).

Image courtesy of GenePoc.

What are the benefits of downsizing these procedures to a micrometer-scale and combining them in a microfluidic device? The most obvious advantage is a reduction in sample size and reagent consumption, which is not trivial when reagents are expensive (e.g., antibodies, chemotherapeutics and small molecules) or when samples are scarce (e.g., tissue biopsies). Furthermore, the high surface-to-volume ratio of the microfluidic channels facilitates heat transfer, enabling quick temperature changes and accurate temperature control. At the small scale of microfluidic devices, diffusive mixing occurs much faster than in a macroscale environment, which yields faster chemical reactions and reduced overall time per analysis. Alternatively, the long and narrow microfluidic channels boast a low Reynolds number ($Re < 1$), resulting in laminar flow that enables precise spatiotemporal control of the fluids in the channels. One could take advantage of the precious characteristic to manipulate, trap and probe cells aggregates or whole-sections of tissues without direct physical contact on the sample reducing potential environmental contamination. Particularly for biological applications, another advantage of microfluidics is the ability to tailor and customize the cellular microenvironment in the device by using micro-fabrication techniques to pattern

molecules in the device or by exploiting the laminar nature of the flow to create physiologically relevant gradients (Young 2010). Furthermore, the dimensions of the microfluidic channel can be adjusted to enable precise manipulation of biological samples of varying size ranging from individual cells to sub-milliliter tissues. Few of the most common applications of microfluidics are illustrated in Figure 1. Moreover, the small scale of these LOC platforms enables the design of portable, low-cost devices that could be used in a variety of point-of-care applications ranging from bedside care to global healthcare.

The development of soft lithography (Whitesides 2001) techniques using polymers enables the fabrication of microfluidic devices suitable for cell culture by forming the device in an optically transparent, oxygen permeable, cheap and flexible elastomer: poly (dimethylsiloxane) (PDMS). These PDMS devices have already been used as biological platforms to study cells and can be used to provide an *in vitro* framework more representative of the *in vivo* behaviour of cells. The versatile and high-throughput nature of soft lithography microfluidics has been vastly exploited to develop new biological techniques towards expanding our comprehension of human physiology. Particularly in personalized cancer models, microfluidics is emerging as a promising tool to develop new clinically relevant therapeutic models that could improve chemotherapy outcome by minimizing drug-induced toxicities. In the next section, we will review the most commonly used models for drug sensitivity screening in oncology and describe how microfluidics can provide new preclinical models for improved patient-specific prediction of therapeutic outcome of a drug.

General Description of Common Cancer Models

Biological assays that help evaluate the effect of a drug on a patient-derived tissue are generally referred to as chemosensitivity and resistance assays (CSRAs). CSRAs have been developed and used in clinical trials for a few decades as a way to characterize the chemosensitivity of a particular patient in order to prescribe the optimal treatment for that patient (Bellamy 1992). Generally, these assays require patient-derived tumor samples to be preserved, *ex vivo*, and exposed to different therapeutic agents. These assays investigate different clinical end-points (cell-death, tumor growth, ATP production) to determine the patient's chemosensitivity profile.

In vitro 2D Monolayer Cell Culture Model

Common *in vitro* CSRAs utilize tumor cell monocultures derived from cancer cell lines or patient-specific tumor cells (Figure 2A) for anti-cancer drug screening and development (Abaan 2013; Boyd 1997). However, increasing evidence suggest that two dimensional (2D) monoculture models can develop irreversible genetic changes and loss of heterogeneity of the cell populations over time (Bounaix Morand du Puch 2016; Huh 2011; Sung 2013). Furthermore, these 2D models lack key features of *in vivo* tissues such as 3D complex architecture, presence of extracellular matrix as well as immune and stromal components, which have been shown to play a crucial role in cancer progression and drug resistance (Junttila 2013; Morgan 2016).

***In vitro* 3D Cell Culture Models**

Matrix-Assisted 3D Culture

Natural hydrogels, such as collagen and Matrigel, can be used to produce extracellular matrices (ECMs) acting as scaffolds that provide the cells with 3D growth architecture (Figure 2B) close to *in vivo* conditions. The presence of ECM during cellular growth has been reported to have great influence on key cell characteristics such as morphology, differentiation, polarity and gene expression, in comparison to conventional 2D cultures (Kenny 2007; Sung 2013; Yamada 2007). Likewise, co-culturing of cancer cells in ECM conditions with other non-cancerous cellular components present in the cell's microenvironment has been shown to affect the proliferation rate, drug sensitivity and protein secretion of cancer cells (Pak 2015; Sadlonova 2005; Xu 2013). These studies highlight the strong influence of cell-cell and cell-matrix interactions on the cell's response to drugs.

Spheroids

Generally, a spheroid originates from a self-aggregating cell that forms a sphere-like shape (Figure 2C). With size varying from a few micrometers up to a few millimeters, spheroids mimic the spatial heterogeneity of tumors, consisting of three primordial layers; proliferating cells on the peripheral layer, quiescent cells in the central layer and necrotic cells in the aggregate center. Furthermore, the 3D nature of the spheroids allows the study of drug

response and the effect of hypoxia through its ability to transport natural gradients of oxygen nutrients and metabolic waste.

For those reasons, spheroids have been generally adopted as a new therapeutic model and a number of microfluidic devices have been designed to allow the formation of spheroids as well as to study the chemosensitivity of these spheroids on-chip (Hirschhaeuser 2010; Shield 2009; Weiswald 2015). For instance, Torisawa et al. have reported a microfluidic device that allows on-chip generation of multicellular spheroids and long-term analysis of cellular viability following treatment of the spheroids in the chip (Torisawa 2007). While spheroids provide a 3D structure that better reflects *in vivo* tumor architecture than 2D monocultures, these models still fail to include components of tumor microenvironment that highly influence tumor cell behaviour.

Organoid Culture

Organoid culture models have emerged in effort to include both the *in vivo* microenvironment and the complex architecture of tumors. Organoids are derived from the stem cells that are grown in ECM, which allow the cells to differentiate and migrate to recreate the specific architecture and function of an organ (Morgan 2016). Fully-grown organoids are composed of multiple cell types and exhibit intra- and inter-cellular communication networks as well as cell signalling pathways that reflect the physiological *in vivo* behaviour of organs. Furthermore, the organoids can be cultured for a long period of time while maintaining histological, immunohistological and genetic properties of the tissue, making them ideal for drug sensitivity assays, clearly observed by Santo et al. through the generation gut-specific crypt-villus structures originating from a single intestinal stem cell (Sato 2009).

In vivo Patient-Derived Xenograft Model

Patient-Derived Xenograft

At the other end of the experimental continuum, *in vivo* CSRAs are most commonly carried out on patient-derived xenografts (PDXs). To generate a PDX, a small portion of a patient's tumor tissue is engrafted subcutaneously in an immune-compromised mouse, where it grows *in vivo* (Figure 2D) in conditions that maintain the local human tumor microenvironment. Such models have the advantage of retaining key characteristics of the original tumor tissue such as tumor heterogeneity, complex 3D architecture, and genetic makeup. Furthermore, genetic analysis revealed that the PDX tumors share the same genetic mutations in the stromal cells and immune cells, with some minor exception. These exceptions may be attributed to the fact that PDX tumors are generated in immune-compromised mice and that tumor stromal cells can be infiltrated by host stromal cells (De Wever 2003; Marangoni 2007; Reyat 2012). Recently published reports suggest that the genetic expression profile of the donor and the PDX tumor were similar but those of the cell lines generated from the same donor tumor showed a very different profile (Bertotti 2011; Fichtner 2008; Julien 2012; Zhang 2013). While PDXs are an interesting model for drug screening and studying treatment effects on cancer progression, these models still present limitations that need to be addressed. For instance, it normally takes 3–4 months to generate a

PDX tumor model that corresponds to a donor tumor, making it inappropriate to determine the chemosensitivity of a patient before the first treatment is initiated. Additionally, as these mice lack a functional immune system, their use in immune drug screening is impractical. Moreover, these models require a lot of resources and are extremely costly to maintain (Ellis 2010). In effort to bridge the gap between 2D/3D monocultures and PDXs, a wide selection of *in vitro* microfluidics-based assays of varying complexity has been developed to improve our understanding of therapeutic response.

***Ex vivo* 3D Models**

Organotypic Tissue Slices

Although the biological models presented thus far help to understand how the 3D architecture and cell-matrix contacts influence the therapeutic outcome of a drug, matching the *in vitro* complexity of *in vivo* tumors is still an unmet challenge. Instead of artificially recreating the complex microenvironment of a tissue, one step towards this goal is to produce organotypic cultures that preserves both *in vitro* tissue viability and the original structure of the tissue in an *ex vivo* environment. These models generally require the tumor tissue to be extracted by surgery and sectioned in smaller pieces to allow diffusion of oxygen and nutrients to the center of the tissue. As it preserves some of the tissue's original *in vivo* architecture and maintains cell-matrix interactions from the primary tissue, organotypic cultures offer the potential of predicting *in vivo* behaviour of the tissue. It is an outstanding tool used to characterize the therapeutic outcome of a drug for a specific patient tissue. Black first described this tool in 1951 where epithelial carcinomas (breast, colon, kidney, ovary, etc.) are extracted by surgery and sliced free hand to a size of approximately 0.5 cm by 0.5 cm and a thickness of 1 mm (Black 1951). The therapeutic response is evaluated by monitoring dehydrogenase activity of the tissues fragments exposed to various chemotherapy treatments or enzyme inhibitors.

A few years later, Thomlinson and Gray used histological analyses to study the mass transport limitation in human lung tumors and showed that large tumors exhibit an hypoxic core in their center (Thomlinson 1955). Based on the diffusive properties of metabolites and the general intake of nutrients by the tissue, they determined a critical diameter that a tumor core should not exceed: if one dimension of the cultured tissue is inferior to this critical diameter, the diffusion of metabolites through the tissue is enough to prevent depletion of nutrients. In this scope, different research groups began to slice tissue biopsies in thin slices (300–400 μm) before cultivating them to prevent diffusion-limited hypoxia (Figure 3). For instance, van Midwoud et al. reported that it is possible to study the metabolism of a precision-cut rat liver slice culture on-chip for a minimum period of 24 hours under continuous perfusion (van Midwoud 2010). Later, Chang et al. introduced a microfluidic device compatible with a 96-well plate allowing long-term culture of mouse brain slices and parallel chemosensitivity testing on the individual slices (Chang 2014).

Figure 3. Organotypic models published previously in the literature. (a) Microfluidic chip that was used by Hattersley et al. to culture liver tissue biopsies. The device comprises a large tissue chamber where the tissue is perfused and can remain viable for over 70h. Image reproduced with permission from (Hattersley, 2008). (b) Microfluidic device reported by Chang et al. that allows organotypic culture of liver slices and parallel chemosensitivity screening on single liver slices. The multi-layered device is compatible with a 96-wells plate and enables the treatment of the sliced tissue with multiple compounds for high-throughput screening assays. Image reproduced with permission from (Chang, 2014). (c) Microfluidic platform developed by van Midwoud et al. to culture rat liver slices under continuous perfusion to study the metabolism and toxicology of the liver slices. Image reproduced with permission from (van Midwoud, 2010).

The main shortcoming of organotypic slice culture relies on the manipulation of large tissue slices without damaging the structure of the tissue, making such a model inappropriate for high-throughput drug screening on a large number of tissue slices. Moreover, long-term culture of large tissue slices usually requires continuous perfusion of the system to prevent hypoxia and nutrient starvation. Such perfusion and associated fluidic connections are cumbersome thus reducing the number of tissue slices that can be multiplexed in a single device, once again affecting the high-throughput screening capabilities of the model.

Micro-Dissected Tissue Culture

In effort to address these shortcomings, our group developed a new model for high-throughput *in vitro* study of therapeutic drug response on *ex vivo* patient-derived tissues (Figure 4). Briefly, tumor samples are micro-dissected and loaded in a microfluidic device where they are trapped and cultured. The micro-dissected tissue (MDT) samples are exposed to various therapeutic agents in the device and therapeutic response is quantified to determine the optimal treatment for that particular patient. The novelty of the presented model relies on the micro-dissection of the patient's tumor biopsy to enable precise spatiotemporal control of MDTs in a microfluidic device. The device consists of parallel fluidic channels to help trap and cultivate multiple MDTs thus assessing chemosensitivity of the tissue in a simple, high-throughput and multiplexed manner. Moreover, the micro-dissection of the tumor sample in sub-milliliter samples eliminates the need for continuous perfusion. The small diameter of the MDTs allows simple diffusion of oxygen through the PDMS matrix, enough to prevent hypoxia in the center. This novel biological model for drug screening combines the physiological relevance of the sliced tissue culture with the simple manipulations of small spheroid-sized tissue sample. The following sections of this chapter will allow in-depth understanding of this new MDT-based organotypic model, highlighting its clinically relevant chemosensitivity screening potential.

Figure 4. Presentation of the proposed personalized treatment model. 1) A tumor biopsy is extracted through biopsy or surgery. 2) Micro-dissection of the tumor biopsy to produce micro-dissected tissues (MDTs). 3) Loading and trapping of the MDTs in the microfluidic device, followed by treatment with different therapeutic agents directly in the device. 4) Evaluation of the therapeutic response with confocal microscopy and fluorescence activated cell sorting. 5) Results are interpreted and used to select the most effective treatment for that patient.

MICROFLUIDIC PLATFORM

Design and Fabrication of the Microfluidic Platform

Microfluidic devices dedicated to cell culture have certain requirements that distinguish them from micro-scale devices used commonly for analytical chemistry or physics. In the case of a microfluidic device that traps and preserves *ex vivo* tissues, design considerations of particular importance are: (1) the choice of material for the device, (2) choice of trapping mechanism, and (3) geometry and dimensions of the channels. We will review each of these considerations and present the important design characteristics of the microfluidic device. We will then describe the fabrication process to produce the microfluidic chip.

Description of Polymer Used for Microfluidic Design

The development of soft lithography by Whitesides and his group in the late 1990s opened new avenues for microfluidic-based cellular applications (Whitesides 2001). Soft lithography comprises a set fabrication technique similar to photolithography, but uses silicon rubber instead due to low-cost and easy fabrication than conventional silicon-based materials. PDMS has several unique properties that make it an ideal choice of material for cell culture applications. First and foremost, unlike silicon or glass, PDMS has a high gas permeability that ensures sufficient oxygen supply to the cells in the device, eliminating the need for separate oxygen chambers. This property is particularly important when cultivating cells that have high metabolic demands like cancer cells. Another advantage of PDMS is its optical transparency and low autofluorescence, both in the visible and infrared regions. This property has been vastly exploited to couple microfluidic devices with imaging modalities that allow assessing the viability of the tissue directly on-chip. Moreover, PDMS is fairly cheap and easy to mold, making it ideal for rapid prototyping and mass production of microfluidic devices. Finally, to form enclosed micro-channels, PDMS can be bonded to different materials (e.g., PDMS, glass, polystyrene) using simple methods such as oxygen plasma treatment.

Sample Trapping Mechanism

As mentioned previously, there are numerous advantages provided by microfluidic devices, particularly when working with biological samples. These devices have the ability to enclose a biological sample in a chamber allowing for easy perfusion and use of smaller volumes of reagents than conventional macro-scale techniques (i.e., 96-wells plate). Microfluidic devices are transparent such that samples can be imaged directly on-chip, eliminating the need to manipulate the sample once it is loaded in the device. For all those reasons, research groups have used microfluidic chips to trap and enclose various types of tissue samples of different sizes ranging from single-cells to tissue slices. For specific sub-microliter particle trapping, such as spheroids, cell aggregates and MDTs, numerous trapping mechanisms have been reported. These mechanisms include acoustic (Liu 2007), mechanical (Khoury 2010), resistive (Ruppen 2014) and sedimentation trapping (Ruppen 2015). The

latter mechanism seems to be more adapted for clinical applications, as it doesn't require complex instruments and continuous perfusion to operate the trap. Furthermore, when tissues sediment in well-like traps, they are protected from the high shear stress induced in the main fluidic channel.

Two conditions must be met for sedimentation trapping to occur. First, the tissue sample being trapped needs to be denser than the surrounding medium for it to sediment to the bottom of the trap. Second, the sedimentation time has to be shorter than the travelling time over the trap. Cells are slightly denser than the medium in which they are cultured because the organelles and proteins they contain are denser than water. This is exploited in petri-dish cultures where cells need to sediment to the bottom of the dish and adhere to its surface to form a 2D cell layer. In steady-state regime, bigger spheres of equal density sediment faster, which explains why a tissue sample of 500 microns in diameter sediments roughly 10 000 times faster than single cells of about 5 μm in diameter, allowing the former to be trapped in less than a second in such small wells.

Configuration of the Microfluidic Platform

An example of channel configuration is shown in Figure 5A, where a whole microfluidic platform is seen from the top. The platform is made up of two fluidic levels: the top level shown in black contours where the samples circulate and the bottom level shown in red where the samples sediment. Five independent channels fit on a 2.5 cm by 7.5 cm surface (equivalent to the surface of a standard glass slide), making it possible to trap up to 25 individual tissue samples and to submit them to five different treatment conditions. The channel length was optimized so that the samples could be controlled using a 20 μL micropipette. Some distance was left between the traps so that each sample would have access to a maximum amount of nutrients from the medium in non-perfused conditions. Each channel is laid out in a serpentine fashion and can be viewed entirely in the field of view of a low magnification stereoscope.

As shown in Figure 5B, the inlet of each channel has a micro-reservoir which facilitates the loading of the samples into the system. The bottom of this micro-reservoir is lower than the rest of the inlet, at the same level as the channels to which it directly connects.

In the current design presented within this manuscript, the channel cross-section is 600 μm by 600 μm . The gravitational square-bottom traps are 600 μm in width by 500 μm in height. The total length of the channel is about 78 mm. Each independent system contains a volume of 29 μL . These dimensions have been tested to accommodate cylindrical tissue samples with dimensions of approximately 350 to 400 μm in diameter by 300 μm in height, and could easily be scaled to better accommodate samples of slightly different sizes.

Diffusion is the main transport mechanism *in vivo* between capillaries and the surrounding tissue. Similarly, within the microfluidic platform, the tissue samples access the nutrients from the medium and discard their cellular waste by diffusion between the channel and the traps. When fresh medium is added to the channels, our simulations show that only the channel (top fluidic layer) fills with fresh medium whereas the medium within the traps mostly recirculates (Astolfi 2016). Gradually, nutrients from the channel diffuse into the traps and metabolic waste diffuse into the main channel. Since diffusion times depend on the size of the molecules, small molecules such as oxygen diffuse rapidly into the traps whereas larger

molecules such as glucose take more time to reach the tissue. Following Einstein's approximation, $t \approx x^2 / 2D$, a molecule such as glucose with a diffusion constant (D) in water of $600 \mu\text{m}^2/\text{s}$ would take approximately 3.5 minutes to diffuse a $500 \mu\text{m}$ distance (x) to the bottom of the traps. When the nutrients reach the tissue, it is expected that diffusion also occur within the tissue, as would be the case *in vivo*.

Figure 5. Channel Configuration of the microfluidic device. A) Microfluidic platform viewed from the top. The top channels are shown in black contours and the traps are shown in red. B) 3D view of a single assembled system.

Microfluidic Platform Fabrication

The platform fabrication process includes the following steps: mold fabrication, PDMS casting and cooking, assembly of the platform, bubble dislodging, sterilization, surface treatment, and pre-loading of channels with saline solution. Two molds are needed to fabricate the platforms. The first Poly (methyl methacrylate) (PMMA) mold, with features that form both fluidic levels (channels and traps) in the bottom layer of the platform, was fabricated by computer numerical control (CNC) milling using a flat endmill of 1 mm in diameter (Figure 5A). The second PMMA mold, with features that form the inlet and outlet holes in the top layer, was also fabricated by CNC milling using a flat endmill of 3.57 mm in diameter (Figure 5A). Liquid PDMS is prepared by combining a base polymer to a curing agent at a ratio of 10:1. This carefully mixed liquid PDMS can then be poured in the mold, degassed and cured in the oven for 1 hour. Once the top and bottom layers of the device are unmolded and cleaned, they can be assembled by oxygen plasma treatment. A nylon hollow cylinder is inserted into each inlet hole, acting as a fluid reservoir. A schematic and an actual real life image of the assembled platform are shown in Figure 6.

Figure 6. Schematic and real life image of the assembled platform.

EXPERIMENTAL PROCEDURE FOR PREPARATION, LOADING AND TREATMENT OF MICRO-DISSECTED TISSUE

Micro-dissected tissue (MDT), being the main focus of this chapter, is a new concept that has recently entered the scientific era. The micro-dissection of scarce tumor tissue samples, cut into sub-millimeter size, allows easy handling and tissue maintenance once trapped in microfluidic devices. Given the architecture of the devices, it is possible to simultaneously test multiple therapeutic agents, giving information on specific patient sensitivity or resistance to particular treatments. Furthermore, this high-throughput biological model exhibits a personalized medicine approach technique that will further help clinicians make therapeutic decisions.

The tissue processing of patient samples is organized in multiple steps, which include tissue harvest and acquisition, the production and culturing of the MDTs allowing tissue viability to be maintained. Once the viability of MDTs is attained in cultured conditions, it is possible to proceed to chemotherapy treatment of the samples permitting the ability to determine the chemosensitivity of an individual patient in a time frame suitable for clinical decision-making.

Criteria for Tumor Tissue Resection

There is one major criterion that is common for all MDT processing projects: the targeted tissue must be palpable or must have visible tumor areas present during the surgical procedure. The cancerous regions must be clearly identified by either a pathologist or a clinician performing the surgery.

Other criteria have been established depending on the solid tumor being processed and on the type of study performed. For example, prostate cancer patients may be enrolled in the study when the cancer targeted can be obtained by a biopsy specimen (of the primary tumor or a metastatic lesion) or by a transurethral resection of the prostate (TURP).

Tissue Micro-Sectioning of Prostate Cancer Biopsy Samples

Tissue Acquisition of Patient Samples

From past experiences and after the optimization of multiple conditions to attain maximum cell viability, a standard operating procedure (SOP) has been written to ensure proper procurement of tissue samples from clinicians. This procedure takes into account the collection, detection of malignancy and transportation of cancerous specimens. The sampling procedure has been fabricated to facilitate safe and efficient handling of the tumor sample with high integrity and quality, which is crucial for the preparation of the MDTs.

The SOP for tissue acquisition of prostate cancer specimen:

Tissue procurement of the prostate is usually done by ultrasound guided trans-rectal biopsies or can be done at the time of radical prostatectomy in patients undergoing surgery.

- 1) By using true-cut biopsy needles one can obtain specimens of 2 mm in diameter $\times$ 20 mm in length.
- 2) 5–6 biopsies of the suspected prostate region with palpable or visible tumor should be obtained.
- 3) Biopsy specimens should be kept in Hanks' Balanced Salt Solution (HBSS, #311-516-CL, Wisent Inc., Saint-Bruno-de-Montarville, Canada) supplemented with 10% fetal bovine serum (FBS, BD Biosciences) and 55 mg/L gentamicin (Wisent) and 0.6 mg/L amphotericin (Wisent) (HBSS_{complete}) and further transported on ice in aseptic conditions.

HBSS is a balanced salt solution that helps maintain tissue pH and osmotic balance. This solution thus provides water and essential inorganic ions such as calcium and magnesium to support vital cellular activity. Additionally, HBSS contains glucose, a main nutrient allowing viability of tissue biopsy to be sustained for a longer period of time. Recent studies have compared HBSS to regular phosphate-buffered saline (PBS) in terms of tissue viability and have shown that HBSS better supports whole tissue maintenance compared to PBS thus making it tissue specific (Astolfi 2016).

For solid tumors that require the identification of cancerous regions by a pathologist, here is the SOP for tissue processing and sectioning by the pathologist:

- 1) A sterile scalpel is used to cut the tumor where there is suspicion of tumor cells.
- 2) Freeze a fresh, unfixed tissue sample, up to 2.0 cm in diameter, at optimal cutting temperature (OCT) in a suitable tissue mold onto the specialized metal grids that fit onto the cryostat.
NOTE: Approximate freezing times at -24 °C using a cold chuck ranges between 20–60 seconds depending on tissue depth.
- 3) Cut sections 5–15 μ m-thick in the cryostat at -20°C. If necessary, adjust the temperature of the cutting chamber $\pm$ 5°C, according to the tissue under study. A hairbrush is useful to help guide the emerging section over the knife blade.
- 4) Within the first minute of cutting the tissue section, transfer it directly onto a microscope slide at room temperature. By letting the slide touch the tissue, the tissue section will melt onto the slide. This must be accomplished within the first minute of cutting the section to avoid freeze-drying of the tissue. The slide is then coated with Poly-L-lysine to improve adherence of the section to the slide.
- 5) To evaluate tissue preservation and orientation, stain the first couple of slides with toluidine blue (1–2% w/v in H₂O), hematoxylin, and eosin, or any aqueous stain.
- 6) The pathologist examines the slides and determines the approximate probability of tumor cell in the sample.
- 7) Using a clean and sterile blade, the mirror section of the tumor sample is cut and placed in HBSS_{complete}.
- 8) The sample is picked up by a technician and transported on ice to the processing laboratory
- 9) The tumor tissue is either processed right away or stored at 4 °C for no more than 24 hours in HBSS_{complete}.

Microfluidic Chip Preparation

The microfluidic devices must be prepared one day prior to micro-dissection of the patient sample. It is important that the microfluidic chips go through several decontamination and sterilization procedures. Firstly, the devices are treated with 100% ethanol to decontaminate the chips followed by 70% ethanol incubation at room temperature for 15 minutes in to allow sterilization. Next, they are treated overnight in a humidified cell culture incubator (37°C, 5% CO₂, 95% ambient air) with a 10 mg/mL triblock copolymer, Pluronic F-108 (Sigma-Aldrich, St-Louis, USA) to reduce cell adhesion on the PDMS surfaces. The following day, the devices are re-sterilized through 70% ethanol incubation for 15 minutes at room temperature. Lastly, they are thoroughly rinsed using sterile HBSS supplemented with 55 mg/L gentamicin and 0.6 mg/L amphotericin (HBSS_{antibio}) and placed at 4°C until the MDTs are produced and ready to be loaded in the devices.

Generation of Micro-Dissected Tumor Tissue

Detail of Micro-Dissection Protocol

Prostate cancer biopsy samples are approximately 2 cm in length and 1 mm in diameter. These fragments are cut into 1 to 2 mm long fragments and immediately embedded in low melting-point agarose supplemented with 10% FBS, which is kept in a liquid form at 40°C. The agarose solidifies on ice to obtain a supporting structure around the tissue. The excess agarose is then removed and the fragments are repositioned vertically and glued to the stage for slicing into 300 µm thick slices using a traditional vibratome. These slices were further punched, using a 400 µm biopsy punch, into disk-like tumor micro-sections, MDTs. On average, a single prostate cancer biopsy can produce 80 MDTs, thus with 5–6 biopsies, we can easily obtain between 400 to 480 MDTs from one single patient sample. The MDTs obtained from each biopsy are pooled together in a petri plate, submerged in HBSS_{antibio}, to ensure randomized selection of the MDTs allowing drug testing of heterogeneous tissues. The MDTs obtained are then carefully loaded in the customized microfluidic chips under a stereomicroscope and cultured in specific culture medium, Roswell Park Memorial Institute (RPMI 1640) (#350-045-CL, Wisent Inc.) medium used for prostate cancer sample culturing. For the loading procedure, the hollow nylon cylinders that form the inlet reservoirs are removed and the microfluidic device is placed under a stereomicroscope. For each individual channel, 5 MDTs are collected using a P20 micropipette and introduced in the inlet, where they sediment to the bottom of the channel. By aspirating fluid from the outlet of the device, flow is induced in the microfluidic channels allowing the MDTs to travel in the channel to attain the wells. Once the MDTs are above the wells the flow is stopped for approximately 1 to 2 seconds allowing them to sediment to the bottom of the traps. The same procedure is repeated to fully load the 5 channels of the device, resulting in a total number of 25 MDTs per device (for visual comprehension, the whole process is illustrated in Figure 7). Furthermore, This RPMI_{complete} medium used does not contain phenol but is supplemented with L-glutamine, 10% FBS, 55 mg/L gentamicin and 0.6 mg/L amphotericin and allows whole cell overall survival of MDTs in our microfluidic devices to be between 60 to 95% (Astoli, 2016).

Figure 7. Overview of the procedure to produce micro-dissected tissue (MDT), to load them into a microfluidic system and to analyze their viability using two complementary methods.

Tissue Sectioning Reproducibility

The distribution of size of the MDTs produced was determined by confocal microscopy analysis. Using maximum projection imaging, the diameter of each MDT was calculated as the average of two perpendicular diameter measurements. Upon analysis, the diameter of the

MDTs remained relatively stable with time and slight variability was detected. This variability was further explained by differences in mechanical properties of the tumor tissues, especially their elasticity, by wear and tear of the biopsy punch and slight differences in sectioning procedure between users. It was clearly noted that tissue with higher elasticity could easily be stretched out during sectioning due to compression force applied by the biopsy punch and can later be brought back into its original configuration.

Irrespective of the tumor type, the diameters of 247 produced MDTs seem to follow a normal distribution with an average (μ) of 380 μm and a standard deviation (σ) of 43 μm (Figure 8) (Astolfi 2016). The ratio σ/μ being less than 12% indicates that the sectioning procedure is highly reproducible.

Figure 8. Histogram (blue bars) with normal fit (red curve) representing the diameter of microsections of xenograft models of various cell lines.

Culturing of Micro-Dissected Tissues and Chemotherapy Treatments

To ensure cell viability and tumor survival of the MDTs at harvest day, HBSS_{antibio} was replaced by fresh RPMI_{complete} medium. The MDTs are continuously incubated at 37°C, 5% CO₂ for the remaining period. The medium is changed 24 hours subsequent to harvest day to ensure proper circulation of nutrients and avoid glucose deprivation, followed by 24 to 48 hours of recovery period to acclimatize the MDTs within the systems before further treatment with different therapeutic agents.

The concentration of the chemotherapy agents used to treat the MDTs was determined by the IC₅₀ obtained by monolayer cell line cultures that are generally used to generate xenografts. Recent studies have demonstrated that at a concentration of 10 times the IC₅₀ of chemotherapy agent results in a significant increase in mortality fraction in spheroids compared to lower concentrations and control (Das 2013). The treatment plan for the MDTs may differ depending on the objective of the project and on the solid tumor being processed. Specifically, for prostate cancer samples processed at the CRCHUM, the MDTs were treated

with Docetaxel, and/or Bicalutamide, common prostate cancer treatment drugs. The IC_{50} of Docetaxel being 1 nM, was calculated in our lab through a metabolic assay, WST-1-based, using various prostate cell lines, all-resulting in similar values. Additionally, through clonogenic assays our lab has determined the IC_{50} of Bicalutamide for 22RV1 cell line to be 10 μ M.

Particularly in our lab, these treatments were given alone, sequentially or in combination at a concentration of 10 nM for Docetaxel and 100 μ M for Bicalutamide. Generally, a cycle of chemotherapy includes a 24-hour incubation period with the chemotherapy agent followed by removal of treatment and a 48-hour recovery period. In order to allow comparison with clinical treatment plan and patient survival, two cycles of chemotherapy are completed on the MDTs. Explicitly, after the recovery period from MDT processing, the chemotherapy agents were diluted in RPMI_{complete} medium in order to attain the desired concentrations. The RPMI_{complete} medium previously in the microfluidic devices was replaced with the medium containing the chemotherapy agent. The chemotherapy treatment was removed and replaced with fresh medium after 24 hours of treatment and thus repeated after 24 to 48 hours of recovery period. Many chemotherapy agents take several days before effects are apparent hence why final day analysis are done 48 hours after the second treatment has been completed.

The MDTs are analyzed at different time points in order to determine initial and final viability of the MDTs. In addition, controls are consistently used throughout the procedure to act as a comparable group of untreated samples ensuring reliability of the results. Initial MDT viability measures are determined by confocal imaging and flow cytometry on harvest day (day 0) and then on first cycle treatment day (day 2). Finally, samples are analyzed, by the same two methods, 48 hours after the second cycle (day 8), comparing untreated samples to treated samples being able to estimate the patients' response to treatment.

The complete process takes approximately 8–10 days and the samples are collected and analyzed in less than two weeks. This method utilized as a 3D cancer model can help determine the chemosensitivity of an individual patient in a time frame suitable for clinical decision-making. Furthermore, this method can help decide which treatment plan will be most effective for an individual thus excluding the use of ineffective therapies for that patient.

METHODS FOR ANALYSIS OF TREATMENT RESPONSE

Two methods were developed to follow cancer cell survival and MDT response to treatment over several days: confocal microscopy of live and dead cells (time point assay) and flow cytometry (endpoint assay) to discriminate the MDT cells according to their viability stage (alive, early apoptotic or dead).

An Automated Analysis of Confocal Microscopy Images to Determine Cancer Cell Response to Treatment

Since PDMS is completely transparent, it allows for direct imaging of the MDTs under the microscope. By confocal microscopy, MDTs trapped in the microfluidic platforms were

imaged at different time points to follow the evolution of cell viability during the 8-day culture period. The combination of CellTracker™ Orange CMTMR (CTO, Thermo Fisher Scientific), which stains viable cells, and Sytox Green (SG, Thermo Fisher Scientific) which stains nucleic acids of dead cells, gives a measure of the viability of cells (Figure 9A). To minimize detection of auto-fluorescence, non-labelled MDTs incubated under the same conditions as the stained MDTs were imaged first to calibrate the upper threshold settings of the microscope (laser power and photomultiplier gains). Labeled MDTs were then imaged directly through the microfluidic platforms using an inverted confocal microscope equipped with a 10X or 20X dry objective (Figure 9A).

Figure 9. Overview of the confocal microscopy imaging of live and dead cells. A) 3D projection of a confocal image of an MDT stained with CTO and SG. B) Individual z-stack images used for viability analysis of the same MDT. Top row is the merged color stacks. Middle and lower rows are the Sytox Green (SG = dead cells) and Cell Tracker Orange (CTO = live cells) channels respectively.

From confocal microscopy images, overall cell viability was evaluated by calculating the ratio of the area of the CTO-positive signal over the summed areas of the CTO- and SG-positive signals. An algorithm applied a median filter to all images to reduce noise and then determined the red and green signal contours in order to apply a threshold algorithm only to those pixels near the contours (Figure 9B), for each fluorescent marker. This threshold method separates the pixels in two groups, background and foreground, so that their intra-class variance is minimal. Once both thresholds were applied, the numbers of CTO-positive and SG-positive pixels were calculated. The sample viability was evaluated by the ratio of CTO pixels divided by the sum of CTO and SG pixels [$V_{\text{viability}} = \text{CTO} / (\text{CTO} + \text{SG})$].

Characterization of Treatment Response of Each Cell Type Using Flow Cytometry Assays

Flow cytometry was employed as an endpoint assay to analyze the cell population (epithelial, immune or stromal cells) and their viability before and after the MDTs had been

exposed to different chemotherapy agents. MDTs were analyzed at different time points to reflect the evolution of cell death over the 8-day incubation period. All fifteen MDTs from the three channels were pooled in the same tube for analysis. A single cell suspension of MDTs was obtained through enzymatic digestion using a combination of crude and type 1A collagenase and mechanical action of gentle repeated pipetting. The resulting suspension is analyzed by flow cytometry. All medium fractions collected from the three channels during the medium changes and stored at 4°C were also pooled together with the digested MDT suspension. This step was added to take into account all the live and dead cells that had been washed out of the systems during medium changes in the microfluidic platform. Single cells from the homogenous cell suspension were then stained with the apoptotic fluorescent dyes Annexin V for apoptosis and DRAQ7™ for dead cells, unstained cells were considered as viable cells for flow cytometry analyses. The cell survival was gated in forward and side scatter graphs, as shown in Figure 10. A survival state was associated for each cell according to its dye staining (live, early apoptotic or dead).

Figure 10. Typical representation of flow cytometry analysis. Each cell (represented by a blue dot) obtained from the MDT was associated to one of three viability categories according to its fluorescence intensity in both DRAQ7 and Annexin V detection channels: early apoptotic cells (Annexin V-stained only), late apoptotic / dead cells (DRAQ7-stained), and live cells (non stained).

Preliminary Analysis of Treatment Response

Patient A was a TURP sample that had developed a castration-resistant prostate cancer (CRPC). The MDTs prepared from this patient sample were cultured for 8 days in the microfluidic platforms and received two complete treatment cycles (for details, see section Culturing of Micro-Dissected Tissues and Chemotherapy Treatments). Confocal 3D projection imaging of treated MDTs allowed for quantitative evaluation and effect of two common prostate cancer treatment drugs. The viability of prostate cancer MDTs is shown below with the live cells in red (CTO) and dead cells in green (SG). The percent viability of

the control samples at $95.8\% \pm 3.1\%$ was compared with the 2 treatment conditions, Drug A at $90.5\% \pm 2.4\%$ and Drug B at $83.1\% \pm 2.8\%$ (Figure 11), indicating a decrease in viability in the Drug B treated samples with respect to the control. In parallel, flow cytometry technique was used to confirm MDT viability and drug sensitivity. The percent viability of the control MDT samples at $62.4\% \pm 10.1\%$ was compared with the 2 treatment conditions, Drug A at $63.1\% \pm 4.8\%$ and Drug B at $35.2\% \pm 2.3\%$ (Figure 12). The preliminary results from both techniques show an increase in Drug B sensibility compared to Drug A. However, the viability results of flow cytometry were quite inferior to those obtained by confocal microscopy. Differences between these two techniques were explained by the identification of early apoptotic cells in the flow cytometry analysis (Figure 12), which might still appear CTO-positive in the dual-stain confocal microscopy analysis.

Figure 11. 3D projections of confocal z-stack images for prostate. Patient A taken 8 days after surgery. Treatment applied for a 24 hr period 2 days and 6 days after surgery. 1) control, 2) Drug A and 3) Drug B.

Figure 12. Flow cytometry survival analysis of MDTs from patient A. MDTs were treated with Drug A or Drug B. Each treatment was applied for a 24 hr period 2 days and 6 days after surgery.

Advantages and Disadvantages of Each Viability Analysis Technique

To compare the potential of confocal microscopy and flow cytometry to evaluate the cancer cell sensitivity to different treatments, it is necessary to analyze advantages and disadvantages of each technique.

Confocal Microscopy

Confocal microscopy gives information about the spatial distribution and the morphology of MDTs. Since samples are imaged on-chip, this technique is fast and makes it possible to easily follow the treatment effect at different time points and the survival evolution of a single MDT in response to one treatment or to a sequence of treatments. On the other hand, mortality is generally underestimated due to the washing out of dead cells during medium changes and staining protocols as well as the staining of early apoptotic cells by “live” dyes. The limited imaging depth of the confocal microscopy (around 100 μm) creates a “black” unanalyzed region in the center of the MDT. This being a strong limitation to estimate the effect of drugs on the survival of cancer cells in the middle of the MDTs.

Flow Cytometry

Flow cytometry is a better quantitative technique to evaluate the overall survival of cells and to allow the discrimination of early apoptotic cells. These early apoptotic cells are the starting point of cell death processes that are accounted as dead cells for the purpose of

evaluating cell survivability fraction. However, this technique is uniquely an endpoint analysis as it necessitates the digestion of MDTs, thus preventing the ability to monitor sample viability over time. This technique also needs a high quantity of cells (at least 15 MDTs) and gives an average reading of the whole microfluidic platforms which reduces the ability to perform statistical analyses.

Overall, these two techniques are complementary to each other and were adapted to measure the overall survival of MDTs within the microfluidic platforms.

CONCLUSION

Strategies toward the management of cancer have changed significantly over the last decade and focused on a personalized medical approach. The major challenge of this approach is to identify treatments that will significantly increase patient survival. One solution proposed is the direct testing of patient tumor material that should allow empirical evaluation of therapeutic responses to a wide concentration and variety of agents. This idea led to the development of a novel high-throughput and low-cost tool for monitoring drug sensitivity of patient tissue. This tool associates a novel technique of micro-dissection, to produce sub-microliter cancer tissue samples, and microfluidic technologies, to generate a biocompatible, gas-permeable and optically transparent platform suitable for cell biology and imaging application. The new *ex vivo* micro-dissected cancer tissue model, which retains the original 3D tumor architecture, should closely mimic the type of responses expected in patients. This rapid and direct approach would influence clinical decision-making and allow the tailoring of therapeutic strategies for individual patients within an acceptable time frame. This would reduce not only the economic burden on the health care system but also the inconvenience and risk of exposing patients to drugs with little chance of response as well as the optimization of therapies in patients more likely to respond.

ABSTRACT

Experimental models of human diseases are crucial not only for understanding the biological and genetic factors that influence the phenotypic characteristics of the disease but also for developing rational intervention strategies. These models often require trial and error adaptation for which limited guidance exists; for example in epithelial ovarian cancer (EOC), a human disease characterized by intraperitoneal dissemination. In this chapter, we provide a detailed stepwise methodology that facilitates laparoscopic or laparotomy approaches in rodent models with EOC xenograft and report outcomes of our experiments.

We compared two immunocompromised rodent intraperitoneal xenograft models for their suitability for laparoscopic or laparotomy techniques. Intraperitoneal xenografts were obtained by injecting nude rats (HSD: RH-*rnu*) with one of the three human EOC cell lines (TOV-112D, TOV-21G, SKOV-3) and nude mice (SWISS-CD-1) with TOV-112D. Laparoscopy or laparotomy was performed using a customized operating

table. Rats and mice developed intraperitoneal macroscopic tumors within 2 to 3 months after injection. In some animals, these were associated with hemorrhagic ascites. Anesthesia, when measured by the number of injections, was more difficult in mouse than in rat laparoscopies and, in both animals, an incisional hernia was sometimes observed. The rat tolerated and survived surgical laparoscopy or laparotomy. In contrast, the mouse was more fragile perioperatively, the number of surgical acts was more limited and survival rate was lower. While the nude mouse was most cost-effective, requiring less operative time and smaller volumes of anesthetic. Our results suggest that the nude rat is better suited to oncological experimentation that involves laparotomy or laparoscopy. Further studies are needed to confirm whether the biological characteristics of the disease are similar in rat and mouse models.

Keywords: ovarian cancer, xenograft, rodent models, laparoscopy, laparotomy

INTRODUCTION

Laparoscopic surgery has been applied in oncology for several years. It has remained controversial in animal models as in clinical practice (Dargent 2000; Hopkins 2000; Canis 2001), although in the last two decades it has gained acceptance in defined clinical settings (Barakat 2013). A number of studies have demonstrated the feasibility of this technique, particularly in human epithelial ovarian cancer (EOC) (Deffieux 2006; Nezhat 2013). Laparoscopy can offer highly satisfactory surgical staging of cancer, including human EOC (Pomel 1995; Pratt 2000). The main concerns with laparoscopy have been the implantation of tumors in trocar puncture sites (Childers 1994), peritoneal carcinomatosis (Fondrinier 2002; Ramirez 2003), modification of tumor growth parameters, and the influence of the laparoscopic environment (CO₂) (LeMoine 1998; Shen 2008). A low rate (1%) of parietal implantation was found in early work (Childers 1994) but further studies found variable rates ranging from 1% up to 18% (Ramirez 2003; Curet 2004; Vergote 2005). Of note, over 100 cases of parietal metastases have been reported in the literature after laparoscopic cholecystectomy (Martinez 1995). In gynecological oncology, such metastases have been documented with invasive ovarian cancer (Hopkins 2000), borderline ovarian tumors (Morice 2004), cancer of the cervix (Agostini 2003), cancer of the endometrium (Sanjuan 2005) and even after laparoscopic surgery for benign disease (benign implants) (Carlson 2002). Nevertheless, some would argue that the presence of parietal metastases after laparoscopy or after paracentesis for ovarian cancer in human seems to have no significant impact on survival (Kruitwagen 1996; Vergote 2005).

In an ovarian cancer animal model, the surgical wound resulting from laparoscopy was suggested to induce little surgical stress on enhancing tumor growth compared with laparotomy, possibly because it minimally influences the secretion of VEGF (Vascular Endothelial Growth Factor) and MMP2 (Matrix Metalloproteinases) (Lee 2013). Moreover, in a rat ovarian cancer model, peritoneal closure is reported to reduce port site metastases (Agostini 2002).

Numerous hypotheses have been put forward for explaining wound or port site implants which implicate immune responses, pneumoperitoneum (Lecuru 2002), carbon dioxide (CO₂), tumoral laceration, smoke, water vapor and contaminated instruments (Brundell 2002; Ramirez 2003; Curet 2004). However tumor implantation was not affected by CO₂, helium,

or nitrous oxide gas in an animal model. Thus, CO₂ insufflation does not appear to increase tumor spread compared with other gasses (Agostini 2002; Hopkins 2002). Further characterization of this phenomenon can only be carried out with an animal model (Canis 1998; Agostini 2001; Lecuru 2001; Bourdel 2008). Use of experimental models for laparoscopy has been reviewed (Canis 2000). The models that are traditionally used are large, (Volz 1996) thereby reproducing conditions of human surgery, including instruments. However these models are expensive and immune-competent and therefore they may reject human tumoral transplants (Reymond 2000). Several immune-incompetent animal models have been developed, such as the nude mouse, the nude rat and the nude rabbit (Hajdich 1992). From an oncological viewpoint, the nude mouse is well characterized, whereas the rat is far less so and the rabbit not at all. Laparoscopy in the rat has been studied for colic resection (Allendorf 1997), rectal tumor resection (Braumann 2008), retroperitoneal dissection (Sandoval 1996) and cecum ligation (Berguer 1997). The metabolic effect of this type of surgery has been described in detail in the rat (Bouvy 1996). In summary, the rat has become an interesting surgical model, primarily owing to its lower cost than that of large animals.

A few animal models develop ovarian tumors spontaneously (Vanderhyden 2003). Intraperitoneal or sub-cutaneous xenograft models have been described for a mouse adenocarcinoma in the previously immune-incompetent rat (Rose 1996), an ovarian adenocarcinoma in a rat of the same species (Sugiyama 1990) and for ovarian tumors of human origin (Sawada 1982; Lecuru 2001; Rubin 2003). The influence of laparoscopy on the tumoral intra-abdominal behavior in the rat was studied after the implantation of mammary cancer (Mathew 1996) and adenocarcinoma of the colon (Jacobi 1997). Likewise, an intraperitoneal xenograft model in the mouse that mimics the dynamic progression of human ovarian cancer might provide a valuable surrogate for studying the biological properties of ovarian cancer as well as for testing new therapeutic strategies in preclinical trials (Lin 2007). In human EOC, a large number of cell lines have been sourced from patient samples, although only a small number is derived solely from chemotherapy- and radiation therapy-naïve women. Our laboratory has previously described such cell lines, which were obtained from solid tumors and readily formed tumors in mice (Provencher 2000). We report details of our procedure for conducting laparoscopy or laparotomy in xenograft rodent models with EOC as well as our findings.

METHODS

Animals

Following approval by the local Institutional Review Board and the Comité Institutionnel de la Protection des Animaux (CIPA) animal care guidelines, rodents such as female (Swiss-CD-1) nude mice (Charles Rivers Laboratories) and female (Hsd:RH-*rnu*) nude rats (Harlan Sprague Dawley Laboratories) were maintained on site at the Hôpital Notre-Dame animal facilities. These rats have a non-functional cystic thymus and accept allografts and xenografts.

Mice were housed in groups of five and rats in groups of four. All animals were acclimatized to a sterile environment controlled for temperature and light cycle. They had access to adequate food and water *ad libitum*. Tumor cell injections were performed when attained weight was 30 grams in mice and 60 grams in rats. At the time of their surgery, mice weighed approximately 50 grams whereas rats weighed about 200 grams. An ear punch allowed identification and surveillance of each animal.

All animals were clinically evaluated twice weekly and observed for 12 weeks or until there were obvious clinical signs of a tumor. Euthanasia was practiced on animals at 12 weeks or when tumors were larger than 1 cm on clinical examination. During autopsy, the tumors, as well as the trocar and laparotomy scar tissues were excised for pathological analysis (Figure 1a,b).

Human EOC Cell Lines Preparation and Injection

We grew and prepared TOV-21G and TOV-112D EOC cell lines obtained from chemotherapy- and radiotherapy-naïve patients, as previously reported (Provencher 2000). Briefly, TOV-112D was derived from an aggressive FIGO Stage IIIC grade 3 endometrioid adenocarcinoma. TOV-21G was established from a less aggressive FIGO IIIC clear cell carcinoma. The SKOV-3 EOC cell line was derived from ascitic cells of a patient with an ovarian adenocarcinoma previously treated with Thiotepa and obtained from American Type Culture Collection. Before their injection in rodents, tumor cells were diluted in phosphate-buffered saline with a pH of 7.4 containing Mg⁺ but without Ca⁺⁺ in a volume of 1 ml for the rats and 0.5 ml for the mice. A total of 14 mice were injected at passage (p66) with 10⁶ cells from the TOV-21G cell line as described earlier (Provencher 2000). Rats were injected with one of the three tumoral cell lines. Either 10⁶ or 10⁷ cells were injected in order to determine optimum seeding of tumors in the rat model. Six (6) rats were injected with TOV-112D cells at passage (p74), 6 were injected with TOV-21G at passage (p56), and 2 were injected with SKOV-3. Intraperitoneal tumor growth was assessed by clinical observation of rodent abdominal distension, which guided the appropriate time for surgery.

EQUIPMENT

Operating Table

We custom built a laparoscopic table for small animals. It is adapted to the size of the animal, its height can be modified, and unlike commercially available laparoscopic tables, it allows for a variable Trendelenburg position (Figure 2a,b and c). Furthermore, this laparoscopic table is equipped with an optical system that can be fixed to reduce the interference caused by hand shaking movements and it enables one sole operator to work in a sterile environment.

Figure 2a,b,c. (Continued).

(b)

(c)

Figure 2a,b,c. (a) Operating table in horizontal position; (b) operating table in Trendelenburg position and (c) operating table in action.

Laparoscopy

Surgical laparoscopy was carried out with a conventional system. This consisted of a monitor (Trinitron™, Sony™), a cold light source (Xenon 611™, Karl Storz™), a CO2 insufflator (Cabot Medical™), a camera (Autoexposure™, Karl Storz™), and an optical system with a diameter of 5 mm angled at 30 (Karl Storz™). Alternatively we also tested optical systems of 2 mm and 5 mm in diameter (Origin System). In addition, the instruments for laparoscopic surgery comprised a pair of scissors, prehensile and biopsy forceps, 1.7 mm in diameter (Origin System). We also used #15 scalpel blades, 3-0 absorbable sutures (Vicryl, Ethicon) and non-absorbable sutures (Surgilon™, Davis+Geck™), cutaneous sutures (Steristrips Skin Closures™, 3M™), 22G catheters (Jelco™, Critikon™), compresses, and 1 ml syringes with 26G needles.

PROCEDURE

Anaesthesia

All surgeries were done in a sterile environment. Slow anesthesia was performed on the animals over 15 to 30 minutes. For rats, Pentobarbital 50 mg/kg was given intraperitoneally for induction, and additional doses of 25 mg/kg were injected as necessary. For mice, a combination of Ketamine 100 mg/kg, Xylazine 10 mg/kg and Acepromazine 0.1 mg/kg was administered by intraperitoneal injection, repeating the injection with half the dose as maintenance. Control of the anesthesia was carried out by pinching a hind paw, then observing the animal reactions and monitoring respiratory movements. As soon as the anesthesia was deemed sufficient, the animal was laid out on its back with its forelegs splayed out at right angles and attached with cutaneous sutures (Steristrips™). This procedure was intended to verify for perioperative respiratory failure.

Laparoscopy

The initial pneumoperitoneum was induced by means of a 22G catheter in the abdominal right lower quadrant of the animal with a CO2 air flow controlled at 3 to 5 mm Hg. A bursa, 4 mm in diameter and 1 cm below the xiphoid appendix, was created, supported with a 3-0 absorbable suture. The abdominal wall was then incised with a #15 scalpel blade at the centre of the bursa and the optical system was rapidly introduced. The bursa was tightened with a simple knot to ensure that there was no leak. The insufflation system was then fixed to the optical system allowing the surgical instruments to be introduced under direct vision, without trocar, laterally in the left and right iliac fossae. They were made impermeable by an identical bursa to that of the optical system. After the surgery, the instruments were withdrawn while still under direct vision and the bursae were closed. An analgesic (Buprenorphine 0.1 mg/kg) was injected subcutaneously immediately postoperatively and 24 hours later for pain control.

Laparotomy

Laparotomies were carried out with the same operative table under the same anesthesia protocol. In each case, a xyphopubic median incision was made with a cold knife #15 blade. The wound was closed with a continuous plane sunk suture with a 3-0 non-absorbable suture.

Surgery

Surgery, whether by laparotomy or laparoscopy, entailed the observation of the intra-abdominal tumor spread status and the tumor was manipulated and resected when possible. The extent of the tumoral invasion was evaluated according to the peritoneal cancer indexes described by Chauffert (PCIC) (Chauffert 1992) and Eggermont (PICE) (Eggermont 1988) (Table 29.2).

RESULTS

Intraperitoneal xenografts were successfully initiated by injecting one of the three human EOC cell lines (TOV-112D, TOV-21G, SKOV-3) to 14 nude rats (Hsd:RH-*rnu*) and the TOV-21G cell line to 14 nude mice (SWISS-CD-1).

All animals survived the initial tumoral injection but one rat, injected with 10^7 TOV-21G cells, had to be sacrificed early due to rapid and excessive tumor spread. Over the observation period, a total of 6 rats and 2 mice developed an intraperitoneal macroscopic tumor with 6 rats and 5 mice also having a hemorrhagic ascite. At the time of surgery, only 4 rats and 1 mouse had developed a tumor. All tumors were macroscopic with an index of 2 to 3 on the PCIC and PCIE. These tumors appeared in the rat on average 63.5 days after the injection of TOV-112D, 97.3 days after the injection of TOV-21G, and 75 days after the injection of SKOV-3 – for an overall mean induction time of 82.3 days (range of 52 to 150 days). In the mouse, the time to development of tumors was on average 83.5 days (range of 58 to 109 days) after the injection of TOV-21G.

Laparotomies were carried out on 6 rats and 7 mice and laparoscopies on 7 rats and 7 mice. In rats, laparotomy had a mean duration of 15.8 minutes and required a mean anesthetic volume of 0.38 ml/animal and a mean of 2.0 injections/animal whereas laparoscopy had a mean duration of 16.9 minutes and required a mean anesthetic volume of 0.44 ml/animal and a mean of 2.1 injections/animal. In mice, the comparative mean anesthetic volumes and mean injections required were 0.13 ml and 1.7 injection/animal and 0.21 ml and 2.3 injection/animal, respectively for laparotomy and laparoscopy. Laparotomy took 9.1 minutes on average and laparoscopy 13.4 minutes in mice. The per-operative characteristics are summarized in Table 1.

The post-operative observation of animals with tumors at the time of surgery showed progression in 5 out of 7 cases and one case of total spontaneous remission. The existence of tumors in the scar tissue was only confirmed histologically in two cases, in mice operated by laparoscopy. None of these two mice showed signs of visible macroscopic tumors but all had ascites. The analysis of the extracted tumors confirmed the existence of extremely undifferentiated carcinomas. The characteristics and the analysis of the tumors in the scar tissue are shown in (Figure 1a and b) and tumor evaluation after laparoscopy or laparotomy are summarized in Table 2.

Complications occurred resulting in the death of one mouse, after laparoscopy, immediately post-operatively with no obvious cause at autopsy. One rat was found dead 72 hours after laparotomy and 2 mice died on the 4th and 6th day after the operation, one for no identifiable reason and the other from complete evisceration. Several post-cicatricial hernias were observed over time. One rat developed a hernia in the 12 hours following the operation. It was treated surgically the following day, but reoccurred several days later. Neither infections nor bleeding were observed. One mouse developed articular swelling of an unknown origin that regressed spontaneously. Another mouse showed signs of cutaneous discoloring with bluish stripes developing over its back. Post-operative evolution is summarized in Table 2.

2 = Tumoral nodule > 1 mm 3 = Diffuse carcinomatosis with ascite.

0 = No tumour.

1 = Nodule of between 1 and 3 mm 2 = Moderate tumour 3 = Abundant tumour replacing the cavity.

DISCUSSION

We described our methods for successful EOC xenograft models amenable to either laparotomy or laparoscopy in rodents. We encountered no problems for injecting animals with tumoral lines extracted from untreated solid ovarian human tumors and animals withstood cell line injection well. The observation of cutaneous discoloring with bluish stripes in one of the mice remains unexplained, however this phenomenon was also observed in an earlier study (Provencher 2000). General anesthesia by subcutaneous injection is preferred by others to avoid any kind of interference with tumor development (Lecuru 2001). Anesthesia posed no particular problem in the rat, neither in laparoscopy nor in laparotomy. The total quantity of anesthetic and number of injections per rat were comparable. In the mouse, the anesthesia was particularly difficult when performing laparoscopy, as evidenced by a high number of re-injections and mean anesthetic volume that was almost twice as high compared with that needed for laparotomy. Nonetheless, mice required smaller anesthetic volumes than rats overall.

As the dimensions of the abdominal cavity in the mouse are small, the number of acts and manipulations remains very limited despite using instruments of 1.7 mm in diameter. We tested an optical system 2 mm in diameter, which frequently had to be repositioned due to its restricted visual field. Nonetheless, this optical system can be useful in diagnostic laparoscopy. The use of a 5 mm optical system and thus vision that extends over the entire pelvic cavity is possible in the rat.

Coagulation attempts with monopolar instruments were carried out and were feasible as long as an isolated 2 mm trocar was used (Veress needle).

Postoperative complications are more serious in mice than in rats. Our results in the rat were similar to those reported by Canis (Canis 1998). The frequently observed incisional hernias are probably explained by the fact that the animals are able to access their abdominal sutures. They can chew and tear off their sutures or their clips. For this reason, it would be preferable to close the wounds without suture material (sutures or clips), possibly using biological glue.

The tumors developed after the injection of 10^7 cells and it appears that this concentration is a minimal concentration required to induce tumors in this animal model. In his study, Rubin (1993) injected 4×10^7 to 2.5×10^9 cells per animal of the SKOV-3 and SKOV-7 lines and Lecuru (2001) injected 27×10^6 IGR-OV1 and 36×10^6 NIH: OVCAR-3 cells per animal. As the volume injected is already 1 ml (maximum injectable intraperitoneal volume tolerated by the rat), we felt that the viscousness would be too high if the number of cells were to exceed 10^7 . It would seem preferable to inject 10^7 cells and to repeat the injection 48 hours later. This warrants further consideration.

All the tumors in the rats were sizeable as confirmed by the intraperitoneal cancer indexes, PCIC and PCIE (Table 29.2). They appeared after a relatively long time after injection (mean of 82.3 days in the rats and 83.5 days in the mice). This is significantly longer than in the IGR-OV1 model (7–21 days) and even in the NIH: OVCAR-3 model (14–21 days) (Lecuru 2001). This parameter is important to consider when planning studies of this kind. The rat, contrary to the mouse, tolerates the growth of intraperitoneal tumors well. This enabled us to stagger the surgery, sometimes by a few days, which may be of practical use. In contrast, for mice, abdominal distension quickly progressed to serious deterioration of the

animal condition translating into a need for emergency surgery. In rodents the distribution of intraperitoneal tumors was similar to that observed in women with EOC. It should be noted that surgery consisted of a close examination of the cavity and that maximal cytoreduction could only be carried out in a few cases. The examination of the abdominal cavity was more precise with laparoscopy.

Tumoral implants were sometimes found in the laparoscopy incision scars in the mice (Figure 1a and b). These mice showed no signs of visible tumors but had ascites. No rats developed tumors in any incision sites in our pilot study. The number of animals studied is too small to draw conclusions but the presence of tumoral ascite has already been evoked as a factor that favors parietal tumoral implants (Kruitwagen 1996).

The nude rat therefore seems more robust as a model of human ovarian cancer and could enable an in-depth study of the influence of laparoscopy on the *in vivo* and *ex vivo* behavior of tumoral lines. Using rats involves a greater infrastructure in terms of animal husbandry and a higher daily cost. These factors need to be taken into consideration as the animals are generally housed in small sterile units. Furthermore, the acquisition cost of nude rats is higher than that of nude mice.

The operating table we custom built enabled us to carry out all required laparoscopic acts we wanted in a sterile environment. Its size is well adapted to the height of the animals and the adjustable Trendelenburg position was extremely useful allowing leverage for manipulation of the instruments (Figure 1a, b and c). The camera being fixed, enables stability while providing gentle rotation to visualize the specific operating field. In this respect, our custom table may offer an advantage over the existing commercial operating table (Kaps Co., Frankfurt, Germany™) (Berguer 1997).

CONCLUSION

The use of laparoscopy in oncology today raises certain concerns and requires more detailed investigations. Our experience suggests that the nude rat is a good animal model of human epithelial ovarian cancer. Animals tolerate laparoscopy and laparotomy well and have a high survival rate. Although it is better characterized from an oncological point of view, the nude mouse has proved to be less reliable in terms of tumor growth in our study. Most importantly, it is more fragile perioperatively and its overall survival is not as good as that of the rat. Furthermore, the restricted size of this animal greatly limits the surgical acts as surgical instruments are not very well adapted for this type of animal despite recent development of operating tables for laparoscopy on small animals. The nude rat, therefore, currently appears to be the ideal model for studying the concept of laparoscopy in oncology. Nevertheless, more in-depth studies are needed to fully characterize the biology of xenograft EOC tumorigenesis in the rat.

FUNDING

This project was possible thanks to the support of the Jocelyne Gauvin research fund.

Chapter 194

ORGAN BIOENGINEERING THROUGH DECELLULARIZATION AND RECELLULARIZATION APPROACHES

Maria Jaramillo, PhD and Basak E. Uygun*, PhD

Center for Engineering in Medicine, Massachusetts General Hospital,
Department of Surgery, Harvard Medical School,
Massachusetts General Hospital, Boston, MA, US

ABSTRACT

Organ transplantation has been used for over a century for the treatment of end organ failure. Despite vast advances in the field, the main challenge remains the availability of good quality donor organs. Scientists around the world are working on the development of alternative options for donor organs available for transplantation, including development of decellularization-based artificial organs, which is the focus of this chapter.

Organ and tissue decellularization has a number of advantages, including preservation of the extracellular matrix architecture and composition, which provide signals necessary for cell function and survival. The preserved vascular architecture in the scaffolds allows for connecting the bioengineered organ to the blood torrent upon transplantation. In addition, ECM scaffolds have been found to elicit low to negligible immune response which is a major advantage, eliminating the need for long-lasting use of potentially harmful immunosuppression therapy in transplant patients.

While very promising to increase the pool of donor organs, the decellularization/recellularization approach for bioengineered organs has a number of challenges. These include methods for decellularization with minimal damage to the extracellular matrix composition and architecture, choice of cells type and source for replacing the functions of organ in question and achieving long-term viability of the engineered organ *in vivo*. Here, we discuss each of these challenges and present current progress in the field for different organs including liver, heart, kidney and lungs.

MSC	Mesenchymal Stem cells
SDS	Sodium dodecyl sulfate

INTRODUCTION

According to the United Network for Organ Sharing (UNOS), there are currently over 120,000 people in need of organ transplants in the United States, from which over 75,000 are on an active waiting list. However, it is estimated that only 30,000 to 35,000 transplants will be performed by the end of this year. This highlights the need for strategies to increase the pool of available organs. Several approaches have been developed to this end, including the formation of organizations devoted to education regarding organ donation to increase donor participation and research in areas including organ preservation, organ rehabilitation and organ engineering.

Organ engineering refers to the development of biological substitutes to replace or aid damaged and diseased tissues, thus maintaining physiological homeostasis in the patient. This involves the use of biomaterials, cells and other microenvironmental signals to mimic the niche of native organs such that their functions are recapitulated and maintained. Several strategies have been adopted for these purposes, including encapsulation of donor cells in biomaterials that provide immunogenic barriers while promoting cell survival and allowing proper cell function. Another approach that is quickly gaining interest is the concept of 3D printing, however, one of the most promising approaches and our main focus for this chapter is the development of artificial organs by decellularization and recellularization of native tissues and whole organs.

Organ decellularization consists of the complete removal of cells and cellular components from native tissues. This offers a number of advantages, including perhaps the closest recapitulation of physical and chemical microenvironmental signals of tissues as well as low biomaterial immunogenicity. In addition, this offers a potentially abundant source of scaffolds, as, in contrast to organ transplantation, organs used for decellularization do not require such strict parameters such as minimal ischemia time, and preservation of the ECM can be achieved more easily than preservation of cell functions. Organs are then decellularized and repopulated with healthy cells, which can be derived from different sources such as allogeneic primary cells, expanded autologous cells, cells differentiated from different sources of stem cells (embryonic, induced pluripotent, adult) amongst others.

In the next sections, we will talk about different strategies used for tissue decellularization, including methods used to evaluate successful removal of cellular

components. We will discuss several approaches for recellularization and will review some of the most notable advances in the field. Because each organ has a different function, organ engineering approaches have to be tailored to satisfy the physical and chemical requirements, therefore we will discuss research work in different organs. Finally, we will review other aspects of decellularization and recellularization organ engineering like introduction of non-parenchymal cells such as endothelial cells for proper vascularization and function of these replacement organs and their immunogenicity.

DECELLULARIZATION

Organ decellularization is typically achieved by subjecting tissues/organs to treatments that disrupt cell integrity, while preserving structure and composition of the extracellular matrix. Most commonly, these treatments are chemical agents, although several physical treatments have been successfully used alone or in combination with chemical treatment to ensure appropriate removal of cellular components from tissues and organs. Ultimately, all methods have a number of advantages and disadvantages, which have to be taken into consideration along with the tissue-specific requirements to come up with the best possible specific strategies for decellularization.

CHEMICAL METHODS

Detergents

Perhaps the most commonly used method for organ and tissue decellularization is the use of detergents that emulsify oils, disrupting the lipid bilayer of the cellular membrane, hence promoting cell lysis. Addition of fluid flow through whole organ perfusion or tissue agitation ensures efficient removal of remaining cellular components. Detergents can be classified into ionic, non-ionic or Zwitterionic detergents.

Ionic detergents have a charged hydrophilic group. They disrupt lipids and proteins, hence strongly disturbing the cellular structures, making them more effective at removing cellular components. Because of the fact that they can interact and denature proteins, they are considered the most destructive and they have a greater effect on the chemical composition of ECM. Additionally, they are harder to “rinse” than other types of detergents, which presents an obstacle to subsequent recellularization of the tissues due to its cytotoxic effects. The most commonly used ionic detergent is sodium dodecyl sulfate (SDS). It is routinely used for decellularization of tissues such as heart valves (Korossis 2002), tubular structures such as trachea (Hung 2016) and blood vessels (Schaner 2004), and whole organs including heart (Oberwallner 2014), liver (Uygun 2010) and kidneys (Wang 2015).

Non-ionic detergents are neutral and hydrophilic. They are highly capable of breaking lipid-lipid interactions, but due to their limited ability to interact with proteins, are unable to break protein-protein interactions and have reduced ability to break lipid-protein interactions. Because of this, they have weaker decellularization potential, but are better at maintaining the chemical composition of the ECM. The most commonly used non-ionic detergent is Triton

X-100, which is typically used in addition to SDS. In a few cases, it has been reported to promote appropriate decellularization alone in tissues such as ligaments (ACL) (Vavken 2009; Xu 2014) and annulus fibrosus (Xu 2014), suggesting to be more appropriate for decellularization of tissues with relatively low cellularity.

Finally, Zwitterionic detergents are considered to be “in between” ionic and non-ionic detergents. They have a net neutral charge, but are able to disturb protein interactions, without altering their native charge, hence are less damaging to the ECM composition than non-ionic detergents. 3-[(3-cholamidopropyl)dimethylammonio]-1-propanesulfonate (CHAPS) is the most widely used Zwitterionic detergent in decellularization approaches, and has been reported to efficiently decellularize tissues such as lung (Tsuchiya 2016). When compared to decellularization with SDS, it has been proven to preserve composition of components such as collagen and elastin, which have a strong effect in mechanical integrity, suggesting that CHAPS may be a better choice for highly cellular tissues whose function is highly dependent on its mechanical properties.

Osmotic Decellularization

Osmotic decellularization, consisting of alternation of hypertonic and hypotonic solution for cell disruption and removal, has been used alone and in combination with other methods such as detergent-based decellularization. Typically, TRIS-based buffers and Phosphate Buffered Saline (PBS) solutions are used. Hypotonic solutions force movement of water into the cell, causing cells to burst, which is followed by use of hypertonic solutions that promote non-histone protein dissociation from DNA. This method is gentler than the use of detergents, and it is considered to lead to better preservation of ECM, so it is typically used for tissue with low cellularity such as heart valves (Meyer 2006), cartilage (Schneider 2016) and cornea (Yam 2016).

Enzymes

Enzymatic decellularization consists of removing cellular components with the aid of enzymes that break down cellular components; some of such enzymes are trypsin, nucleases and dispase. Nucleases are enzymes that break down nucleic acids (DNA and RNA), but usually do not act on other cellular components, therefore are typically used in conjunction with other treatments that aid penetration of nucleases into the cells. There are other enzymes such as trypsin that promote breakdown of serine-containing proteins, which are very efficient at breaking down cells; however, because they are non-specific, they also interact with ECM proteins. Lipases are a good candidate for decellularization as they specifically disrupt the lipid bilayer of the cell membranes without disrupting ECM proteins, however, rather limited success at complete cellular removal has been achieved by the use of lipases alone (Crapo 2011).

PHYSICAL METHODS

Sonication

Sonication has been used mostly in combination with other methods for decellularization of tissues such as larynx (Hung 2013), trachea (Hung 2016), cardiovascular tissues (Azhim 2011), cartilage (Azhim 2013) and small intestine (Oliveira 2013). It has been shown to be advantageous in cases when perfusion decellularization is not possible due to the limited diffusion of chemical agents. In such cases, sonication has shown to enhance the degree of removal of cellular components through passive diffusion of decellularizing agents. It has been observed that sonication greatly speeds up the decellularization process, decreasing exposure time to chemical agents which typically show higher disruption of chemical composition.

Freeze/Thaw

This method is rarely used alone, but typically used as a critical step of decellularization in combination with other methods discussed here. Freezing promotes ice crystal formation of water, which, unlike most other materials, increases volume in its frozen form. This increase in water volume damages cell membrane, leading to break down of the cells. Typically, ice crystal formation can be reduced by cooling at low rates; hence, decellularization by thawing is better achieved by rapid freezing of tissue.

Irreversible Electroporation

Irreversible electroporation (IRE) is a novel technique that is currently being explored. It consists of applying non-thermal pulsed electric fields to disrupt the cellular membrane while maintaining the integrity of the ECM. This method has been explored as an *in-vivo* decellularized method (Golberg 2016), where the scaffolds are decellularized in live animals, however, it has also been used in *ex-vivo* perfusion models (Sano 2010).

Evaluation and Success Parameters

Biochemical evaluation of decellularization is typically performed by quantifying cellular components such as DNA and actin to estimate the amount of cellular material removed. In addition, preservation of ECM composition is evaluated by estimating concentration of ECM proteins such as laminin, elastin, collagen and fibronectin, or other components such as glycosaminoglycans (GAG). Quantification of these is typically done by standard assays such as ELISA, PicoGreen and immunostaining, however, due to the destructive nature of these methods, recent studies have highlighted the need to develop new methods that do not require damage to the decellularized tissue, thus promoting maintenance of its integrity for subsequent use. Some of the suggested technique include analysis of perfusate (Jörn 2015),

but also more sophisticated methods such as computer tomography, which has been used for monitoring DNA content in real time (Geerts 2016).

Another parameter that is typically evaluated in most applications is the maintenance of the microstructural integrity of the scaffolds. For most tissues, the maintenance of a capillary network is essential, and this can be investigated by corrosion casting and a number of microscopy techniques including angiography and scanning electron microscopy. Furthermore, perfusion of dyes that can be removed by additional perfusion can be used to visualize capillary integrity after decellularization. In addition to capillary network integrity, other parameters such as topography have been evaluated through technique such as atomic force microscopy; the significance of it being that material characteristics such as roughness can alter cell behavior.

Additionally, for tissues that serve a mechanical function or tissues that need to be able to withstand mechanical loads, bulk physical parameters need to be evaluated. This is the case for tissues such as bone, tendon, cartilage, cardiac valves, lungs, muscle, blood vessels and many others. Depending on the tissue requirements, stress, strain, tensile strength, elasticity and compliance need to be evaluated.

Overall, there is no standardized set of parameters to define success in decellularization except for DNA content which is defined as 1) less than 50 ng of dsDNA per mg of dry weight; 2) DNA fragments less than 200 bp in length; and 3) no visible nuclear material in histologic analysis with DAPI or H&E, according to Faulk et al. (Faulk 2015). When performing such evaluation, it is important to keep in mind that every tissue serves a different function and hence, preservation of certain characteristics may be more important. For instance, in the case of liver engineering, the conservation of biochemical composition may be of higher importance, as hepatocyte function and viability is highly dependent on the chemical microenvironment. Alternatively, tissues such as cartilage are relatively acellular and the biggest functional requirement is the ability to withstand mechanical loads, hence, higher importance is given to the maintenance of physical characteristics. This highlights the need for a comprehensive compilation of data to define tissue-specific parameters and tolerance levels that will allow optimizing decellularization procedures based on specific requirements.

RECELLULARIZATION

After successful decellularization of organs and tissues, the next step is to repopulate the decellularized scaffolds with cells that will carry out vital functions of the organ. The main challenge in this step is the identification of a reliable and abundant cell source that will replace the functions of the native organ. There are a number of constraints in this step which include development of strategies for cell delivery, retention and maintenance. However, perhaps the biggest challenge is the establishment of an abundant cell source, which we will discuss in the following sections.

***In-vitro* Expansion and Maintenance of Primary Cells**

Most cells in the body have a limited ability to expand and maintain a functional phenotype in an *in-vitro* setting. This phenomenon is not well understood but its investigation could lead to the development of strategies to generate an abundance of functional cells to be used in cell/tissue engineering applications. Unfortunately, despite the great promise of this field for regenerative medicine applications, very limited advances have been made in this area.

A recent study describes genetic modification of primary human hepatocytes to express Human Papilloma Virus (HPV) genes, which mediate expression of receptors-associated hepatocyte proliferation *in vivo*. Exposure of the genetically modified hepatocytes to proliferation-inducing cytokines promotes their expansion amounting to up to a trillion cells per single hepatocyte. Removal of proliferation signals leads to polarization and induction of function in the hepatocytes (Levy 2015). Genetic engineering strategies has also been exploited for the expansion and maintenance of beta-cells using Cre/loxP-based reversible immortalization (Kobayashi 2006), however, these approaches rely on use of viral vectors, which could cause activation of oncogenes, hence, tumorigenicity. Other studies have concentrated on manipulation of the *in vivo* microenvironment rather than the cells, including the development of scaffolds with appropriate physical and chemical cues that have been found to promote limited expansion and functionality of cells such as alveolar cells and hepatocytes (Shamis 2011).

A number of tissues rely on progenitor cells with proliferation potential for repair of damaged tissue and cell turnover. Isolation of these cells, with subsequent expansion and induction of terminally differentiated phenotype, constitutes another strategy for organ engineering relying on primary human cells. The difficulty of this approach is isolation and identification of these cells from live patients; however, some advances have been made with the use of progenitor cells derived from stem cells, which will be further discussion in a later section.

To conclude this section, it is important to note that use of primary cells would require immunological matching of cells to patient, and potentially immunosuppression to avoid rejection of the transplanted graft. Recent studies have also explored the possibility of silencing genes involved in immune rejection (Figueiredo 2013), which in conjunction with successful strategies for expansion and maintenance of primary cells, would make the possibility of the creation of universal cell banking for off-shelf regenerative medicine applications a reality.

Cell Recovery from Discarded Organs

A new strategy that has emerged as an alternative approach is to recover cells from marginal organs deemed unacceptable for transplantation. While very little work has been done in this field, a few recent studies have shown that a number of cells including beta cells (Matsumoto 2007) and hepatocytes (Izamis 2013; Izamis 2015; Uygun 2016) can be recovered from organs exposed to warm ischemia for up to one hour by perfusion with preservation solutions that restore ionic concentrations of the cells and ATP generation. The

resulting cells have been isolated at yields and levels of functionality comparable to those of primary cells.

Stem Cell Differentiation

Perhaps one of the most explored options is differentiation of functional cells from a number of different stem cell sources. Depending on their origin, cells can be pluripotent, multipotent, or have the ability to become a very limited number of cells. Stem cells are most commonly categorized into pluripotent, mesenchymal or tissue-specific stem cells.

Pluripotent stem cells include embryonic stem cells derived from the inner mass of the embryonic blastocyst and induced pluripotent stem cells, which are somatic cells that have been genetically engineered to express a number of genes characteristic of embryonic stem cells, giving these cells their pluripotency characteristics. Both cell types have two main features: their ability to self-renew indefinitely (making them a potentially unlimited cell source) and to differentiate into cells derived from the three germ layers of embryonic development (mesoderm, ectoderm and endoderm). Differentiation programs are based on developmental studies that identify specific signals that determine their fate, which are then recapitulated in an *in-vitro* setting. Most commonly, these signals are chemical cues such as cytokines and small molecules, but can also be in the form of physical cues, such as substrates with varying mechanical properties. Despite their enormous potential, success of pluripotent stem cell differentiation has been limited partly due to the fact that they rely on developmental studies using non-human models; hence translation of these observations into development of human systems is imprecise. Challenges in this field remain, including low functionality and maturity of the resulting cells. In terms of complex cell types, such as hepatocytes, that carry a large number of diverse functions, a challenge has been the recapitulation of all the functions. This last requirement can be bypassed by the alternative strategy of creating auxiliary grafts that instead of replacing the entire organ will aid it by providing the function that is aberrated in the patient. This strategy could be used in deficiency diseases, such as Alpha-1 antitrypsin (AAT) deficiency. Hepatocytes in AAT-deficient patients often carry out other vital functions such as albumin production, lipid metabolism, carbohydrate metabolism and drug metabolism. In such cases, creation of a graft with differentiated cells that produce AAT and be transplanted in the patients, auxiliary to their native liver to aid rather than replace the marginal organ.

Mesenchymal stem cells are naturally occurring adult cells that are not terminally differentiated hence maintain the ability to differentiate into a limited number of tissues within the mesodermal lineage (bone, cartilage, muscle, adipose tissue and blood; although some studies report limited differentiation into ectoderm and endoderm lineages). Their sources include cells derived from adipose tissue, bone marrow, tooth bud and umbilical cord which are readily accessible and can be patient-specific.

Finally, some tissues have fast cell turnover and rely on resident stem cells to continually replace aged or damaged cells. Some of these include oval cells in the liver, epithelial lining of the stomach and intestine and skin. These cells typically can differentiate into just one or two cell types, and can be isolated using cell-specific markers.

ADVANCES

In the following sections, we will discuss and summarize some of the most prominent advances in the field of decellularized tissue-based organ engineering of a number of specific systems.

Liver

First reports of whole liver decellularization date back to 2009 (Baptista 2009). Being a highly cellular organ, and because the lipid content can be higher than in most other tissues, liver decellularization is most often achieved by the use of detergent, which preserves a significant amount of the chemical composition and the architectural integrity of the liver including its vascular network. Because of the highly vascular content, decellularization is typically done by perfusion through one of the main vessels (typically portal vein).

Report of recellularization first appeared in 2010 (Uygun 2010) when rat livers were recellularized using freshly isolated primary rat hepatocytes, which performed hepatic functions (albumin and urea secretion, and drug metabolism protein expression) comparable to those found when hepatocytes were maintained under static collagen sandwich culture conditions, which to date, remains the gold-standard for culture of human hepatocytes. In addition, the recellularized grafts were transplanted into rats that underwent unilateral nephrectomy to prepare a viable site for auxiliary liver graft transplantation. The renal vein and artery were used as ports to create blood source. Efflux was established within 5 min of unclamping and the recellularized graft was kept for 8 h before evaluating damage to the hepatocytes due to the arterial blood flow and the resulting shear stress, which was found to be minimal. A later study showed that the recipient survival could be extended to 24 h by the addition of a heparin layer on recellularized liver grafts (Bruinsma 2015). However, thrombogenicity of the grafts still remains a problem.

Subsequent studies have been conducted in larger animal models including rabbits, sheep, and porcine livers (Kajbafzadeh 2012; Nari 2013; Wang 2015). One study using porcine livers (Barakat 2012) evaluated recellularization using human fetal hepatocytes and stellate cells, and the recellularized grafts were kept under perfusion culture for up to two weeks, during which they showed metabolic activity including oxygen and glucose consumption, lactate and urea production, and albumin secretion.

Several cells have been investigated as potential sources for recellularization. A number of studies have investigated the use of MSC (He 2013; Jiang 2014) and have reported differentiation of these cells within the scaffolds (with addition of soluble chemical cues) to be superior to differentiation of the same cells under 2D culture conditions. However, neither report compared hepatic functions of differentiated cells to those found in primary hepatocytes, making it hard to determine whether maturation is achieved to physiologically-relevant levels. Other studies have used MSC for recellularization in conjunction with primary hepatocytes, and have shown that this co-culture configuration improves engraftment and function of the primary hepatocytes (Kadota 2014).

Finally, there are two alternative approaches to both decellularization and recellularization that are worth discussing. First, there have been a few reports of efficient

liver decellularization using IRE (Golberg 2016; Sano 2010). This method has been used for decellularization of livers under ex-vivo perfusion, which can be subsequently recellularized, however, due to the regenerative potential of liver, has also been explored as a method for *in vivo* decellularization and recellularization, as it has been demonstrated that after IRE treatment, liver regeneration occurs in the absence of scar formation. Other methods for *in vivo* decellularization and recellularization have been developed, including detergent-based decellularization of a single lobe in-vivo through surgical by-pass circulation with a perfusion chamber system (Pan 2016). In this study, decellularized lobe was subsequently recellularized *in vivo* with primary hepatocytes from donor rats. Alternatively, the idea of transplanting decellularized livers to allow for “spontaneous” in-vivo recellularization has also been explored, but the resulting grafts were inferior when compared to *in vitro* recellularized grafts (Sabetkish 2015).

Lung

Lung decellularization was first reported in 2010 in studies in mice and rat lungs (Ott 2010; Price 2010) and using a combination of methods, including hypertonic/hypotonic solutions, detergents and enzymes. Because of the function of the lung, preservation of its mechanical integrity is of utmost importance, hence, decellularization protocols have been developed avoiding or minimizing use of ionic detergents, which have been shown to lead to greater loss of elastin and collagen that confer lungs their mechanical properties, including tensile strength and elastic behavior (Petersen 2012). A number of strategies have been developed to maximize cell removal while promoting maximal retention of ECM components, and in turn mechanical properties. These include: use of zwitterionic detergents such as sulfobetaine-10 (Nagao 2013), or non-ionic detergent such as Triton X-100 or CHAPS. Alternative ionic detergents such as ethoxylated sodium lauryl ether sulfate (SLES), have been developed solely for decellularization purposes. SLES is weaker than traditionally used SDS, and because of its ethoxylation, the lauryl alcohol content is reduced, hence exhibiting lower protein denaturation (Kawasaki 2015). Alternative approaches have focused on modification of delivery of decellularization reagents. For instance, it has been suggested that perfusion route has an effect on efficiency of decellularization, with intratracheal route being suggested as the preferred method (Maghsoudlou 2013; Tsuchiya 2016; Wang 2016). In addition, some studies focus on optimization of physical parameters such as flow rate and pressure, which can be increased to speed up the decellularization process, hence, minimize exposure (da Palma 2015; Khalpey 2015). Despite, or partly due to the large number of studies evaluating decellularization methods in lungs, there is little consensus about which method leads to best decellularization. Because these studies are often performed in different animal systems, there is very little real time monitoring of the progression of decellularization, and so much variability in terms of concentrations, physical parameters, and timing used, reports often come to contradicting conclusions, highlighting the need for a comprehensive evaluation of these methods in a systematic way that would allow for standardization of lung decellularization protocols.

Recellularization of lungs has been attempted using adult and fetal alveolar cells (Price 2010; Song 2011), airway epithelial cells (Gilpin 2014), lung cancer cells (Mishra 2012), MSC (Bonvillain 2013), human iPSC-derived alveolar epithelial cells (Ghaedi 2013), hESC

(Nakayama 2013), basal epithelial stem cells isolated and expanded from human lungs (Gilpin 2016) and fibroblasts (Sun 2014). In general, these studies have demonstrated that decellularized scaffolds are capable of supporting cell engraftment and in some cases, differentiation. It has also been suggested that when recellularizing lungs with progenitor cells (either fetal or stem cell-derived), the addition of mechanical forces such as stress and strain are important as these provide differentiation signals to the cells (Bonvillain 2013). Interestingly, decellularized rhesus monkey lungs have been used as a model to demonstrate decellularized matrix specificity to cell type by performing differentiation studies of hESC showing that differentiation of these cells in lung scaffolds showed better epithelial airway differentiation than if the cells were seeded on scaffolds derived from other tissues (Nakayama 2013).

Finally, there have been a few reported studies of evaluation of function of the decellularization-based engineered lungs in an *in vivo* setting. This was first attempted in 2010 (Ott 2010) when rat lungs were recellularized with lung endothelial and epithelial cells and transplanted into recipient rats after 5 days of *ex vivo* culture. The rats first underwent pneumonectomy (left lung) and the grafts were transplanted by anastomosis of the graft to pulmonary artery, pulmonary vein and left main bronchus of the recipient. No bleeding, edema or leakage was observed within one hour of transplant, and blood gas levels showed improvement when compared to the levels after pneumonectomy. The grafts were maintained for up to 6 hours, however, complications were observed at this time-point, including edema, which was probably because of pulmonary secretions.

Heart

Heart valves were amongst the first tissues explored for decellularization/recellularization tissue engineering approaches. Despite this, whole heart decellularization was not explored until 2008 (Ott 2008) in a seminal study that produced decellularized hearts from rats via coronary perfusion of SDS. Since then, a number of protocols have been developed exploring different chemical agents (Triton X-100, EDTA, deoxycholic acid, Sodium Azide, Saponin, Glycerol), perfusion routes (pulmonary, aortic or coronary) and physical parameters, however, there is little consensus regarding the best method for whole-heart decellularization.

Decellularization success parameters are typically retention of chemical components, especially, elastin and GAG. Biomechanical characterization often involves stress-relaxation which analyzes elastic moduli and viscosity, and tensile-failure tests which also can be used to estimate elastic modality and viscosity in addition to load limit (Bronshtein 2013).

Recellularization of heart tissue has been explored using a number of cell types, including myoblast cell lines (Akhyari 2011), adult and fetal cardiomyocytes from different sources (Wainwright 2010), as well as supporting cell types present in the heart. Cardiomyocytes recellularization has been attempted using primary rat cardiomyocytes. They have been shown to gain myocardial organization and express cardiac markers, and exhibit synchronized beating (Eitan 2009). A different study using neonatal cardiomyocytes from mouse to recellularize porcine hearts showed maintenance of cell viability and measurable electrical activity within five days of recellularization (Weymann 2014). Similarly, recellularization of human hearts with human cardiomyocytes has shown that the cells align in a muscle-like fiber manner, exhibit calcium dynamics and action potential propagation (Sanchez 2015).

Pluripotent stem cells and MSC (Sarig 2012) have been seeded onto decellularized hearts both to test the cytocompatibility of the scaffolds with these cells, but also for their ability to differentiate within the scaffolds. In the absence of differentiation signals, it was shown that hiPSC were able to engraft and survive for up to seven days, however, it was also observed that by the end of the culture, there was a significant loss of pluripotency markers (Carvalho 2012). In addition, hiPSC-derived cardiomyocytes have been used to recellularize human heart ventricular scaffolds resulting in increased expression of ion channels and increase in electrophysiological responses (Garreta 2016).

Recellularization with fibroblasts was shown to regain some of the lost components during decellularization process such as GAGs, which enabled to gain strength (Eitan 2009). Finally, it has been suggested that recellularization success is dependent on the source of the scaffolding tissue. A recent study compared recellularization success in hearts prepared from adult and fetal rats and found that fetal scaffolds provide better engraftment and proliferation of neonatal cardiomyocytes and adult cardiac progenitor cell (Silva 2016).

Very few translational studies involving transplantation of decellularized matrix-based engineered hearts have been performed. The first reported of such studies involved transplantation of porcine scaffolds using ascending aorta and the superior vena cava as an inlet and outlet of the blood stream, respectively, with closure of vena cava, pulmonary veins and pulmonary artery circulation. The results of this study showed that the scaffold integrity was adequate to endure surgical procedure, and artery perfusion was achieved. Additional procedures were performed with scaffold pre-recellularized with MSC, however, blood flow in this model was not achieved. Alternatively, MSC were injected into the scaffold immediately prior to transplantation, which allowed for establishment of blood flow and some degree of engraftment of the cells was confirmed after 3 days (Kitahara 2016).

Finally, several groups have attempted to engineer bioreactors for cardiac heart engineering in order to ensure small variability in decellularization/recellularization process, but also to efficiently deliver a variety of signals that will promote cell engraftment, viability, proper function and/or differentiation, and in some cases, even provide real time monitoring of the grafts. One example is a modular bioreactor developed to maintain recellularized hearts under controlled perfusion and medium conditioning (oxygenation, temperature and pH control), which also provides myocardial stretching, electrophysiological stimulation and/or monitoring (Hülsmann 2013).

Kidney

Kidney decellularization was first achieved in rat models (Ross 2009) and shortly after tested in large animal models (Nakayama 2010; Vishwakarma 2014). Decellularization of kidneys is typically achieved by detergent-based methods, with SDS being deemed the most successful (Wang 2015), hence the most commonly used. Transplantation studies with SDS-decellularized porcine kidneys have been performed which showed maintenance of vascular structure as suggested by lack of blood extravasation (Orlando 2012), intact microarchitecture of the glomerular structures, and when seeded with primary human cells, promoted their survival and viability (Sullivan 2012). Furthermore, SDS decellularization has been successfully attempted in human kidneys (Orlando 2013), which exhibit preserved

vasculature, microstructure and maintenance of growth factors within the matrix (Peloso 2015).

Decellularized kidney recellularization has been performed using murine stem cells (Bonandrini 2014; Guan 2015), iPSC-derived tubular epithelial cells (Caralt 2015), renal epithelial cells (Uzarski 2015) and adipose-derived MSC (Rafighdoust 2015). Addition of chemical signals, such as chondroitin sulfate has been used to improve seeding and differentiation of stem cells into renal epithelial cells (Rafighdoust 2015). In terms of stem cells, it has been found that seeding and culture in decellularized scaffolds promotes a decrease in pluripotency and increase in mesoendodermal markers (Bonandrini 2014). Finally, it has been suggested that recellularization with different cell types can be achieved by perfusion seeding of epithelial cells through the ureter, and non-parenchymal cells through arterial route (Willenberg 2015).

Pancreas

Pancreas is perhaps one of the most complex organs in terms of decellularization, which is probably reflected by the very small number of published studies in the field. It has been suggested that success has been hampered by the complex architecture of pancreas and very delicate vascular structure, which is easily disrupted by common decellularization methods (Willenberg 2015).

Decellularization of rat pancreas was first reported in 2013 (Goh 2013). In this study, decellularization was achieved by perfusion with SDS at low concentration, and the decellularized scaffolds were subsequently seeded with acinar and beta cell lines, which showed an increase in functionality. A very recent study successfully achieved human pancreas recellularization with triton X-100 and recellularized with primary human beta cells and endothelial cells, showing viability and insulin secretion after 4 days in perfusion culture (Peloso 2016).

VASCULARIZATION/ENDOTHELIALIZATION

Every tissue in the body relies in some degree of vascularization for its survival and proper functioning. Vascular structures are in charge of ensuring delivery of nutrients and oxygen to each cell to guarantee its survival, but in many cases, cell signals are also delivered from the cells into the blood-stream through the same capillary structures, for systemic delivery and homeostasis. Liver and pancreas are two organs that are highly vascularized, both due to the high metabolic requirements of the cells and the delivery of cell-products, which include albumin and insulin respectively. This highlights the need for decellularization protocols that maintain the integrity of capillary network.

Blood vessels, regardless of size, are lined by a specialized epithelium that performs a number of functions, from providing a selective barrier between blood and tissues to production of signals that aid functioning of parenchymal cells. Importantly, endothelial cells prevent blood coagulation and fibrinolysis by a number of mechanisms, including the production of prostacyclin and nitric oxide that prevent platelet aggregation, activation of

anticoagulation pathways and thrombin inhibition through heparin-rich domains in their cell surface. Transplantation studies have shown that in the absence of endothelium, decellularized scaffolds fail due to blood clot formation. For this and more reasons, in addition to maintenance of capillary structure, it is important to develop approaches for appropriate endothelial coverage of the vasculature of decellularized tissues.

Challenges

Success of decellularization-based artificial organs is highly dependent on the achievement of adequate re-endothelialization of the vascular networks, which remains one of the greatest obstacles in this field. A number of factors contribute to the difficulty of achieving adequate endothelial coverage, including challenges in delivering endothelial cells exclusively to capillary networks, poor engraftment, insufficient spreading of endothelial cells, poor formation of tight junctions and other functional morphological characteristics of endothelial cells and identification of highly available cell sources.

At the initial stages of development of this field, it was hypothesized that decellularized matrix possessed a sort of “postal code” that would allow specific cells to attach to the appropriate locations within the scaffolds (Bonvillian 2012). However, a number of studies found that when a mixed population of cells was seeded onto decellularized organ scaffolds, cell engraftment was heterogeneous. Some studies have nevertheless found that maintenance of phenotype and differentiation into specific cell types is improved when cells are seeded onto their appropriate site (Petersen 2010). Approaches for cell delivery into specific sites vary greatly depending on the organs, with some organs having several routes for cell delivery that can be used to orchestrate the spatial organization of cells. Improved engraftment of endothelial cells can be promoted by a number of approaches including use of capture antibodies that will recruit endothelial cells through surface markers, preparation of coatings that improve endothelial cell attachment, functionalization of matrix with angiogenic factors and signals that promote endothelial cell proliferation and spreading. In addition, it is also important to provide signals that will induce organization of cells into functional structures that will provide barrier functions, including tight junctions, adherent junctions and adhesive structures that regulate specific permeability of cells. Finally, like with other aspects of organ engineering, a significant challenge is the identification of an abundant cell source. In terms of reendothelialization, some of the candidate cell sources include: primary cells from cadaveric tissues, stem cell-derived endothelial cells and progenitor endothelial cells from patient circulation.

Advances

As previously mentioned, one strategy for spatial control of cell organization consists of using specific routes for cell delivery. This can more easily be used in organs with separate luminal networks such as lung that contains circulatory and airway networks. Specifically, re-endothelialization is achieved by perfusion seeding on endothelial cells through pulmonary vein and/or artery (Ren 2015) while alveolar epithelial cells are to be seeded via the trachea (Ott 2010). In cases where multiple routes are not an option, spatial organization was

attempted through injection of parenchymal cells into the parenchymal space, in combination with perfusion seeding of endothelial cells through the vasculature (Zhou 2016). Sequential seeding can also be exploited so that parenchymal cells are first introduced through vascular perfusion filling the parenchymal space, followed by perfusion of endothelial cells (Kadota 2014). Finally, it has been suggested that simply adjusting the posture of the decellularized organ during cell-seeding increased cell homogeneity and cell retention (Stabler 2016).

In terms of improved endothelial cell capture, spreading and survival, some strategies have been developed based on previous studies for endothelialization of engineered vascular grafts, valves and devices such as cardiovascular stents. These include CD133 or CD31 antibody conjugation to the decellularized scaffolds to increase capture of endothelial cells through surface marker capture (Jackson 2014; Ko 2015; Vossler 2015). This is achieved by activation of carboxylic groups in the ECM to induce amide bond formation with primary amines in antibodies, which was found to increase endothelial cell adhesion under shear conditions. Similarly, conjugation of other factors used for improvement of endothelial cell attachment include fibronectin (Ren 2015) and heparin-gelatin mixtures that both increased attachment and migration of endothelial cells, while also providing an antithrombotic coating to reduce blood clot formation (Bao 2015; Hussein 2016). The aforementioned study highlights an alternative approach to overcome the challenge of blood clot formation that relies on reduction of thrombogenicity independent of endothelial cells. One example is a recent study that explored layer-by-layer heparinization of decellularized organ matrices, resulting in decreased blood clot formation (Bruinsma 2015).

In terms of selection of cell source, the same alternatives previously mentioned for parenchymal cell source have been explored. In this section, we will focus on endothelial progenitor cells due to their numerous unique advantages. Endothelial progenitor cells are naturally occurring cells that participate in vessel formation, remodeling and repair. They can be isolated from a number of sources including peripheral blood, bone marrow and umbilical source, and selected by surface marker labeling methods. Finally, certain subsets of EPC have been found to be highly proliferative making them a potentially abundant source. Several groups have explored their use for endothelialization approaches, including a recent study where EPC were isolated and expanded from bone marrow and seeded into liver scaffolds through portal vein perfusion. The resulting scaffolds exhibited coverage of the lining of tubular structures by endothelial cell marker expressing cells, suggesting at the very least, maintenance of endothelial cells markers, however, further analysis is required to assess their maturation (Zhou 2016). EPC from cord blood have also been utilized for recellularization of decellularized rat lungs, although their viability after perfusion culture was lower compared to recellularization using other endothelial cell sources such as HUVEC (Ren 2015).

OTHER CONSIDERATIONS

Monitoring Decellularization

As previously mentioned, current methods for evaluating completion of decellularization consist of destructive methods that render the scaffolds unusable for further applications. This is acceptable in animal studies where homogeneity of the organs is higher, hence, the results obtained in one experiments are typically representative of subsequent experiments. However,

due to variability of lifestyles in human subjects, variability of the organs is greater, and the possibility of developing a “one-size fits all” protocol is unfeasible. A great way to exemplify this is by mentioning dietary effects on variation of lipid contents in liver, which may increase difficulty of liver decellularization in humans, requiring the use of additional components that, while helping with removal of excess fat from fatty livers, may induce greater loss of important components in non-fatty organs. This highlights the need for creation of non-destructive and real-time monitoring methods that allow for the monitoring of decellularization progress, so that protocols can be modified to optimize decellularization in real time.

A limited number of studies have shown promise in using non-destructive techniques for monitoring various attributes of decellularized matrix scaffolds. This includes evaluation of perfusates, which have been used to determine appropriate removal of detergent from matrix through biochemical assays (Zvarova 2016). This has also been used to determine degree of removal of cellular components through rheological measurements (Jörn 2015). More sophisticated techniques such as phase-based x-ray tomography (Hagen 2015) which have been used to acquire high resolution images of the scaffolds, hence allowing for evaluation of their architectural integrity. Similarly, it has been shown that methods such as computer tomography can be used to estimate certain parameters such as Hounsfield unit of tissue, which was found to be correlated with DNA content in tissue, hence, in combination with other methods, such as perfusate analysis, could be an adequate method for non-destructive monitoring of decellularization (Geerts 2016).

Monitoring Recellularization

Equally important to the development of non-destructive methods for monitoring decellularization, it is essential to develop approaches to evaluate status of the engineered organs after recellularization. A number of these methods are in existence, as they rely on the same principles used to evaluate function of organs in-vivo, such as measurement of electrical properties of heart, biochemical secretions from liver and pancreas that can be measured from perfusates (albumin, insulin, glucose levels). However, these are end points that are typically measured days after cell seeding to determine the function of the organs before implantation. Evaluation of additional parameter earlier in the process may prove beneficial, as they would provide information that can be used to change culture parameters that could aid optimize conditions for survival of the cells within the scaffolds.

Some novel techniques for monitoring recellularization include the evaluation of dynamic changes in physical parameters, such as hydrodynamic pressure, which increases with appropriate endothelialization (Uzarski 2015). Furthermore, methods such as perfusion with Resazurin has been found to be a non-cytotoxic method to assess metabolic activity of the grafts, hence can be used to determine cell engraftment, proliferation and survival (Ren 2015).

Immunogenicity

The ultimate goal of organ engineering is to develop fully functional tissue substitutes that will not elicit a host immune reaction, hence, bypassing the need for immunosuppression, which leaves patients vulnerable to infections and long-term complications such as cardiovascular diseases and increased risk for cancer. In addition to incomplete removal of cellular component, which has been extensively discussed in previous sections, immune response can be elicited both by the scaffold itself or cells used for recellularization. These issues have been addressed by a number of groups, and will be discussed in the following paragraphs.

The main activators of immune response from xenogeneic sources are DNA and Gal α 1-3Gal β 1-4GlcNAc-R (alpha-Gal), a membrane epitope present in most mammals except primates (including humans). Theoretically, complete removal of cell and cellular components should render decellularized scaffold from other species usable for organ engineering applications for human use, however, other aspects should be considered such as differences in size and architecture of organ/tissues, and removal of pathogens. The possibility of using decellularized tissues from xenogeneic sources has most extensively been evaluated in heart valves, and it has been established that collagen and elastin from bovine and porcine sources does not elicit a response from human dendritic cells, B cells, or T cells, suggesting immunocompatibility (Bayrak 2013). Despite this, availability of human organs from cadaveric donors is abundant, hence, still remains the most desirable source for decellularized scaffolds.

As discussed earlier, cells from xenogeneic sources express a number of epitopes that elicit responses from the immune system of humans, making human sources the most viable alternative. Cells recovered from cadaveric donors would require HLA typing and possibly blood matching and cross matching and despite this, transplantation of these cells may still require immune therapy. From the sources mentioned earlier, iPS-derived cells, and some MSC-derived cells are perhaps the most non-immunogenic, as they can be patient-specific. A number of other stem cells, including ESC and some of the resident stem cells present in a number of tissues have been found to have little to no expression of HLA and elicit no immune responses, suggesting immune privileged status of these cells.

CONCLUSION

Engineering of functional organs through decellularization/recellularization of cadaveric organs is a field with great promise for the alleviation of current limitations to organ transplantation, including limited availability of donor organs. Decellularization can be achieved by a number of physical and chemical methods, all with several advantages and disadvantages, as well as success rates that depend on the specific characteristics of the organs themselves. Adequate recellularization is dictated by a number of parameters, including availability of a reliable and abundant cell source that needs to be successfully delivered into the scaffold, where it should remain both viable and functional. Recellularization also requires addition of non-parenchymal cells that support proper functioning of the organs. Particularly important is inclusion of endothelial cells that in

addition to their supportive function, provide a functional vasculature, which is fundamental to the survival of the grafts. Other interactions yet to be investigated, include the incorporation of innervation into the engineered organs, however, most visceral organs function well without a nerve supply, and even in traditional transplantation approaches, innervations of the donor organ is not performed (Sanatani 2004). Finally, studies with several tissues including a recent work using decellularized liver scaffolds have shown some degree of inflammatory response in rats implanted with porcine liver matrices (Wang 2016). Crosslinking has been suggested as a possible method to overcome immunogenicity associated with use of xenogeneic scaffolds (Boer 2015, Wang 2016) and has led to promising results.

Chapter 195

WOUND HEALING AND SCARRING

A. Samandar Dowlatshahi*, MD

Plastic and Reconstructive Surgery,
Harvard Medical School, Boston, MA, US

ABSTRACT

Wounding is ubiquitous in clinical as well as experimental surgery. It is defined as any violation of tissue integrity in a live subject. The success of an experimental model in surgical research depends on control and predictability of the wounding as well as wound healing processes. Wounds typically are thought of in the context of skin wounds. In reality, even procedures deep within the torso, such as a model to study solid organ transplantation, rely on wound healing at every level: from the microvascular anastomosis, to the fascial layers that were obligatorily violated and to the skin at the site of the incision. In some circumstances, wound healing itself is the subject of study, such as in hernia or wound healing research. In experimental models, where it is not the subject matter in itself, any impaired tissue healing can contribute to morbidity and experiment failure. It is therefore critical for the surgical scientist to have a basic understanding of wound physiology and mechanisms of tissue regeneration and scarring, as well as animal-specific differences.

Keywords: wound healing, wound physiology, wounding, experimental wound models, surgical tissue handling, atraumatic technique, scarring, skin, tissue regeneration

ABBREVIATIONS

CCL	C-C Motif Chemokine Ligand
CD	Cluster of Differentiation
DNA	Deoxyribonucleic Acid
ECM	Extracellular Matrix

* Corresponding Author's Email: drdowlat@gmail.com.

FGF	Fibroblast Growth Factor
IL	Interleukin
MIP	Macrophage Infectivity Potentiator
miRNA	Micro RNA
MMP	Matrix Metalloproteinase
PDGF	Platelet Derived Growth Factor
RNA	Ribonucleic Acid
siRNA	Small Interfering RNA
TF	Tissue Factor
TGF	Transforming Growth Factor
VEGF	Vascular Endothelial Growth Factor

INTRODUCTION

From the beginning of recorded history, wound healing has been the subject of awe and fascination to healers, scientists, physicians, and even the layman in the form of “home remedies,” throughout all cultures. The principles of primary and secondary intention healing were laid out by Galen in the first century A.D. Major advances occurred throughout the 19th and 20th centuries in particular with the advent of large-scale geopolitical conflicts, improving our understanding of the physiologic processes involved. The impetus underlying these advances was first and foremost the desire to save the lives of wounded warriors and civilian casualties, and decrease human suffering and physical morbidity.

Our advanced understanding of the physiologic processes involved has not only impacted clinical care but it also allowed for the development of more elaborate and sophisticated experimental models.

Every type of live tissue has, embedded within its genetic coding, mechanisms for tissue repair secondary to injury and wounding. Wounding does not only imply mechanical injury, but also includes tissue injury in a broader sense, such as chemical injury, radiation and reperfusion injury. It is critical to understand the difference between repair and regeneration. Regeneration refers to the reconstitution, or re-creation of the injured cells to result in an organ or tissue with its original integrity and architecture. It is a remarkable biochemical and physiologic pathway unique to select organs and animals and is the subject of regenerative medicine. Wound healing, on the other hand, leads to creation of repair tissue, which differs in varying degrees from the original tissue. In terms of skin, the resulting tissue is referred to as scar, which has a different cellular and extracellular composition as compared to native skin. In cartilage healing, the substrate is known as fibrocartilage. Virtually all types of human and animal tissue have a genetically programmed response to wounding.

PHYSIOLOGY OF WOUND HEALING

Three Integrated Phases

Tissue wounding results in a series of physiologic processes that occur both consecutively and also simultaneously, traditionally defined as the phases of hemostasis and

inflammation, proliferation, and remodeling (Childs 2017). They can also be referred to as the wound healing cascade, resulting in the formation of repair tissue, restoring the wounded organ's integrity and function.

Hemostasis and Inflammation

Immediately at wounding, the process of hemostasis begins. The key step which sets this process in motion is the exposure of blood components to the sub-endothelial layers of the vessel wall. This leads to vasoconstriction, as well as formation of a blood clot which in turn serves as a barrier against microbial invasion, at the same time minimizing blood loss. Our current understanding is that the blood clot is the epicenter that orchestrates wound chemotaxis, triggering the subsequent wound healing phases of inflammation and proliferation by attracting progenitor cells. It contains several growth factors and cytokines (Midwood 2004; Huntington 2005).

Hemostasis is initiated by the extrinsic pathway whereby Tissue Factor (TF) which is expressed by sub-endothelial tissues (vascular smooth muscle cells, pericytes and adventitial fibroblasts), comes in contact with circulating factor VII and creates the FVIIa-TF complex (Schechter 2000; Mackman 2007). This, activates FIX and FX. FXa and its cofactor FVa form the prothrombinase complex which leads to the activation of prothrombin to thrombin. The latter then converts the soluble plasma fibrinogen to fibrin which, in turn, is insoluble and leads to thrombocyte entrapment in the nascent clot. Thrombin also activates factors V and VIII, which both feed back into the cycle of factor X activation. Thrombin itself is also pro-inflammatory, leading to vasodilatation, edema, and a release of cytokines such as C-C Motif chemokine Ligand 2 (CCL2), Interleukin 8 (IL-8) and IL-6 (Levy 2016).

The role of fibrin in wound healing is substantial. It promotes stromal cell proliferation, binds to integrin CD11b/CD18 on monocytes and neutrophils, Fibroblast Growth Factor 2 (FGF-2) as well as Vascular Endothelial Growth Factor (VEGF) (Sahni 1998).

Degranulating platelets also release chemoattractants and growth factors such as Transforming Growth Factor β (TGF- β), Platelet Derived Growth Factor (PDGF), VEGF, CCL5, monocyte chemoattractant protein-1, CCL2, CCL3, Macrophage Inflammatory Protein 1 α (MIP1 α), TGF- α , C5a, C3a and nerve growth factor. (Maraganore 1993; Frank 2000).

Interferon- γ , IL-1 β and TNF- α promote the transmigration of neutrophils across the capillary wall by means of adhesion and diapedesis. Current research indicates that macrophages within the wound require the guidance of neutrophils in the process of wound repair (Peters 2005). In the presence of infectious agents, as well as devitalized tissue, the neutrophil response appears to be enhanced. This is another reason why atraumatic technique is critical in controlling the amount of inflammation in the postoperative period; traumatic tissue handling can lead to tissue injury, necrosis, and inflammation.

Mast cells and macrophages also contribute to the inflammatory phase of wound healing. Once the monocyte leaves the blood vessel, it differentiates into a macrophage, now functioning as antigen presenting cell and phagocyte. It also secretes numerous growth factors such as TGF- β , TGF- α , PDGF, basic FGF (bFGF) and VEGF. Mast cells hereby modulate the inflammatory response and their influence extends throughout the entirety of the wound healing cascade. They have even been implicated in the pathogenesis of hypertrophic scarring as well as delayed healing (Noli 2001).

Proliferation

This phase has classically been described as taking place between two and 21 days post-injury. It overlaps with the inflammatory phase and begins with the gradual degradation of the blood clot which functions as a provisional matrix. During this phase, fibroblasts deposit extracellular matrix and proliferate. Within three to five days, they become the predominant cell type in the wound. They deposit collagen onto a fibronectin and glycosaminoglycan matrix resulting in scar tissue. In the skin, this collagen is initially histologically disorganized and is primarily of type III; it will eventually undergo remodeling and the ratio of type I to type III collagen reaches a ratio of 4:1, similar to native skin.

Granulation tissue refers to the beefy, dark red colored tissue which appears within days in open wounds. It consists of fibroblasts, macrophages, as well as sprouting blood vessels which explains its tendency to bleed, similar to a pyogenic granuloma. It is not only seen in cutaneous wounds. Even areas affected by chronic inflammation such as tendinitis, can often have an appearance and histopathologic similarity to granulation tissue.

In the case of skin healing, the proliferative phase is accompanied by epithelial resurfacing. This is clinically one of the most visible elements of wound healing and can be followed by visual inspection of the wound on a day-to-day basis. Within hours of injury, the keratinocytes at the margin of the wound undergo morphologic changes and migrate across the wound. Once the wound is resurfaced, a keratinocyte layering process takes place, increasing the thickness of the restored epidermal layer. This process is also visible when a thin skin graft thickens over time.

In conjunction with fibroblast and keratinocyte proliferation and migration of the latter, wound contraction can also contribute to wound closure. It is mediated by the presence of myofibroblasts, which are fibroblasts at the wound margin that differentiate into protomyofibroblasts and subsequently to myofibroblasts, when subjected to mechanical tension and PDGF. (Hermanns-Le 2015) The extent of wound contraction for non-cutaneous wounds remains to be determined. Interestingly, keratinocytes also appear to have a cytoskeleton allowing for contractility and may also contribute to skin wound contraction (Gniadecki 2001).

Remodeling

During this phase, the structural elements of the skin, and in particular the ECM, undergo changes. This is a balanced act of extracellular matrix (ECM) degradation and synthesis, partly modulated by matrix metalloproteinases (MMP). Collagen cross-linking also takes place, increasing wound tensile strength. Lysyl oxidase is the primary cross-linking enzyme. (Kobayashi 1994) This phase of healing lasts at least one year and results in a mature scar. The initial erythema associated with ongoing inflammation and scar maturation eventually resolves and corresponds to regression of the dense capillary network.

Despite this length of time, the end-result of wound healing consists of repair tissue, and is different from unwounded skin. Its tensile strength can only reach a maximum of 80% of unwounded skin and the orientation and organization of sub-epithelial collagen is dissimilar to the reticular pattern in native dermis. In fetal wound healing on the other hand, the end-result is scarless tissue regeneration, with a restoration of normal epidermal and dermal

architecture. (Beanes 2002, Buchanan 2009) It was once thought that scarless skin healing was associated with factors present in the amniotic fluid, but this hypothesis has been refuted (Buchanan 2009).

MODIFYING FACTORS IN WOUND HEALING

Colonization and Infection

Colonized wounds show no immune response, in contrast with infected tissue. Infection, in contrast to colonization, indicates that a threshold number of bacteria are present in the wound and have overcome host resistance, leading to slowing down fibroblast proliferation and ECM synthesis. Bacterial loads greater than 10^5 organisms per gram of tissue is the historically accepted threshold. (Robson 1990) In our clinical experience, however, this number is no longer of absolute relevance. Depending on the vascularity of the wound bed, the presence of ionizing radiation, level of oxygenation as well as tissue edema, the state of the immune system and the anatomical location, varying degrees of bacterial burden are tolerated and may or may not lead to an overwhelming immune response as seen in infected wounds. In consequence, the clinical presentation of an infected wound can vary, traditionally described as the presence of pus with associated tissue inflammation (tumor, calor, rubor, functio laesa), and be as subtle as increased drainage, or discolored appearing granulation tissue with increased friability. The virulence of the offending organism is another variable which is difficult to quantify.

The mechanisms by which bacteria affect the wound microenvironment are multiple. The organism's attempt at neutralizing the offending agent leads to release of proinflammatory cytokines, leading to inflammation and pain. Pain in itself has been shown to delay the immune response. (White 2009) Biofilm represents an accumulation of microorganisms within a matrix of extracellular material and has prompted interest in recent years because of its ability to shield itself from this host inflammatory response (Nouvong 2016).

Vascularization: Angiogenesis and Vasculogenesis

Wound healing requires blood supply, enabling tissue oxygenation, delivery of nutrients, and removal of waste products. Small wounds can heal by means of diffusion, as seen in the initial stages of free skin graft healing. Larger wounds require neovascularization. This process is divided into vasculogenesis and angiogenesis. The former refers to the formation of new blood vessels from marrow-derived stem cells, the latter is described as the sprouting of capillaries from already present blood vessels at the wound margins. In reality, these processes overlap. Their regulation is sophisticated and is primarily driven by proangiogenetic factors and cytokines originating from platelets, macrophages, leucocytes as well as local circumstances such as hypoxia. It is important to note that most of these key players are located within the hemostatic plug that eventually undergoes ECM and cellular changes during the proliferative and remodeling phases of healing.

Platelets induce migration of endothelial cells to the wound site. Macrophages secrete TGF- β , TGF- α , PDGF, bFGF and VEGF which drive angiogenesis. (Okizaki 2016) VEGF-A and IL-8 are proangiogenetic factors which originate from leucocytes. (Labler 2009) The VEGF mechanism of action consists of ligation with endothelial tyrosine kinase receptors, in particular VEGFR-2 and VEGFR-3. Many of the endothelial signal transmission pathways in vascularization involve tyrosine kinase receptors. The endothelial cell receptors Tie-1 and Tie-2, and VEGFR are the only known endothelial tyrosine kinases (Singh 2009; Savant 2015).

Once activated, endothelial cells proliferate and migrate. The ECM also contributes to this process of vascularization. (Sottile 2004) A significant element of the ECM, the basement membrane, is required in order to stabilize the tubular configuration of endothelial cell clusters. In addition to a structural and stabilizing role, the vessel basement membrane induces polarization of the endothelial cells.

The Role of Ischemia and Tissue Oxygenation

Ischemia and hypoxia designate different processes. Ischemia relates to hypoperfusion. Hypoxia will often be present in hypoperfused, ischemic tissues, but itself is defined by a lack of oxygen supply relative to oxygen demand. In consequence, tissue hypoxia can be induced by either increasing tissue oxygen demand (e.g., wound healing, wound infection with oxygen consumption to create reactive oxygen species such as oxygen free radicals), decreasing arterial oxygen supply (e.g., pulmonary fibrosis, anemia inefficient cardiac circulation, altitude), or increasing the resistance to oxygen diffusion (e.g., tissue fibrosis, radiation, edema). Tissue hypoxia will amplify angiogenetic pathways which, in turn, are linked into all three phases of wound healing. This has several implications for experimental surgery. One must keep in mind that within a wound, there may be local pockets of extreme hypoxia leading to focal apoptotic cell nests with a significantly different micro-environment and resulting cell behavior.

The Role of Micro RNA

In order to go from protein-coding gene to protein, the deoxyribonucleic acid (DNA) is transcribed to messenger ribonucleic acid (RNA), which is translated to protein. Micro RNAs (miRNAs) are 19–22 nucleotides long and are noncoding RNA which, in conjunction with small interfering RNAs (siRNAs) modulate both transcription and translation. 1048 miRNAs are encoded in the human genome. The role of miRNAs in wound healing is established, but poorly understood (Shilo 2007).

Endothelial cell capillary sprouting for instance can be inhibited by knockdown of the miRNAs Dicer and Drosha. (Kuehbach 2007; Kuehbach 2008) On the other hand, there exist antiangiogenic miRNAs such as miR-92a, miR-17, and miR-320, just to name a few.

Other proangiogenic miRNAs are miR-17-92, miR-126, miR-130a, miR-210, miR-296 and miR378 (Banerjee 2011).

miRNAs also play a role in the proliferative phase of wound healing (miR-184, miR-205, miR-210) as well as the inflammatory phase (miR-105 targets TLR2, miR-140 targets the PDGF receptor, miR-146a and miR-125b target TNF- α) (Banerjee 2011).

The purpose here is not to provide an exhaustive list, but to demonstrate that known chemokines have now been shown to have another layer of regulatory factors as seen in the miRNAs which adds another level of fine-control and complexity. It also offers a potential therapeutic strategy; modulating a group of functionally related genes in a pathway by targeting a single miRNA, as opposed to targeting a single gene at a time, as in conventional gene therapy.

In wound healing research, the most fascinating phenomenon is scarless wound healing as observed in mammalian fetal skin. (Beanes 2002) miRNA may explain some of these findings, as a number of these (miRNA-29b, miRNA-29c, miRNA-192) have been found to be differentially induced during different phases of gestation and may play a role in scarless cutaneous healing (Cheng 2010).

PRACTICAL IMPLICATIONS FOR EXPERIMENTAL SURGERY

Animal Models for Wound Healing

Role and Limitations of In vitro Models

In-vitro studies allow to study the effect of agents on specific cell types in a controlled environment. In particular, the presence or absence of confounding cell lines and chemokines can be controlled for, which is of particular interest in wound healing research because of the numerous cell-to-cell and cell-to-ECM interactions involved. They are however unable to completely reproduce biological conditions relevant to clinical wound healing. Furthermore, unlike many other physiologic processes, wound healing always involves biomechanical factors such as wound contraction as well as periodic changes in repair-tissue tensile strength that cannot be studied in an *ex-vivo* construct, or even by computerized simulation. The animal study is therefore the logical next step. It should be noted that the number of articles in Pubmed pertaining to animal wound healing models has exponentially increased since 1980.

Small Mammal Wound Healing Models

Rodents and small mammals find widespread use in wound healing models. They are inexpensive and require minimal space, food and water. They also exhibit accelerated wound healing as compared to humans, which shortens the duration of experiments. Small mammal anesthesia is relatively facile, and inexpensive. Due to their size, facilities with limited space are not an issue and animal transportation is easily accomplished, especially in studies with larger numbers. Wound healing experiments are typically carried out on the back of the animal, where partial and full thickness wounding can be reproducibly accomplished. Lastly, the availability of numerous knock out rodents allows the animal model to be more refined and specific to the needs of the study in question.

Limitations include the difficulty in securing dressings, wound care, a different hair growth cycle as compared with humans, the extremely thin skin (50µm) and the presence of the subcutaneous panniculus carnosus muscle which aids in wound contraction. (Davidson 1998; Wong 2011). Furthermore, certain studies requiring larger numbers can be successfully accomplished with fewer animals of larger size. Murine models have been preferentially used for burn research but it has been shown that they have a physiologic response to injury that is dissimilar to what is seen in humans. (Seok 2013) Lastly, mice can only tolerate 30% Total Body Surface Area Burns, which in humans will only begin to induce a systemic inflammatory response (Pereira 2005).

Porcine Wound Healing Models

Of all animals, porcine skin is structurally as well as histologically the most similar to humans. (Lindblad 2008) Porcine collagen, cutaneous blood supply and follicular hair structure is similar to humans, as well as a similar physiologic response to wounding. The skin turnover time is 30 days, similar to human epidermis. The greatest downside is the cost compared to smaller animals, in terms of animal acquisition, as well as feeding, space requirement, dedicated vivarium and more complex anesthesia monitoring modalities. Miniature breeds are now available, weighing 12–45 kg as compared to the >100 kg domestic pig.

On the other hand, the swine model is much more convenient to use: partial thickness defects can be easily created using dermatomes or hydrodissection (salt split technique), ischemic wound models are easier to achieve by elevation of a skin flap and interposition of a barrier. Serial wound biopsies are easier to obtain because of the larger size and surface area. The thickness and architecture of the subcutaneous fat is also more similar to humans, whereas in a rodent model, a full thickness skin wound can often extend straight to muscle fascia. Lastly, wound healing is greatly dependent on wound hygiene as well as dressings utilized in wound care. Poorly applied dressings lead to contamination, shear, desiccation or maceration, and can affect the study outcome. Wound care is greatly facilitated in larger animal models.

With the increasing incidence of diabetes and diabetic wounds, studying the altered wound healing in the setting of diabetes is of particular interest. Streptozotocin can be utilized to induce a diabetic state in swine. (Sheets 2016) Hypertrophic scar models can be studied using Red Duroc pigs (Zhu 2003; Gallant 2004; Zhu 2004). Chronic, non-ischemic wounds can be created by irradiation and wounding. (Bernatchez 1998) Infected wound models are created by using different pathogens, most commonly Staph Aureus (Breuing 2003; Hirsch 2008).

Tissue Handling and Atraumatic Technique

As experimental models increase in complexity, it becomes more important to pay attention to adequate tissue handling, as this correlates directly with the ability of the tissues to heal. This is relevant for skin wound healing research, but also when the abdominal cavity or chest wall is entered and procedures on internal organs carried out. For microsurgeons this

is obvious, as they have seen a vessel readily thrombose following a poorly placed stitch or aggressive grasping of the vessel wall during microvascular anastomosis. Meticulous technique is required when handling other tissues as well, and will determine outcome.

Instruments and Tissue Handling

All too often, instruments of poor quality, or even damaged instruments are made available to the experimental surgeon. Not only does this violate the core ethical values pertaining to animal research, in which animals are to be treated as living beings and respected as one would respect a human being (poor instruments are never acceptable in clinical surgery), but also, due to the more difficult circumstances in a laboratory, as well as smaller size of the anatomical structures, it becomes even more important to use clean and precisely engineered instruments that are in good shape.

Grasping instruments such as forceps and retractors should be utilized only when necessary, and for the shortest time possible. The most atraumatic instrument used for retraction is a sharp hook or double hook. Crushing of tissues must be prevented at all cost, as it will lead to obligatory tissue ischemia and injury. Therefore, when using forceps, preference is usually given to toothed forceps, except when handling nerves and blood vessels. Here, every effort is made to not grab the structure itself, but to use the vessel adventitia or the epineurium as a handle. Aggressive tissue handling will lead to perineurial scar formation, vessel thrombosis, skin injury and resulting wound dehiscence or delayed healing. In tendon surgery, careful handling will prevent adhesion formation and possibly failure of the experiment. Brutalization of bowel loops leads to bowel adhesions and possible serosal injury.

Bleeding and Hemostasis

The use of cautery and other hemostatic agents is fortunately less common today in the animal operating theatre than in the clinical setting where the monopolar electrocautery appears to be the only instrument able to cut tissue. The degree of thermal trauma caused by cautery has been well documented, and linked to poor wound healing, as well as adjacent organ injury. Most tissues will stop bleeding spontaneously or with gentle pressure. Visible vessels should be precisely cauterized or ligated. Thermal methods of cautery include the monopolar, bipolar and the handheld battery-powered cautery. The latter is the least traumatic and can be used as precisely as a knife. The only downside is the limited battery life. Surgifoam has been found to be very useful immediately post-anastomosis in microsurgical cases where it can be applied in a thinly cut sheet to cease bleeding from the anastomotic suture line.

Dissection and Desiccation

The most atraumatic dissection is carried out sharply with scissors or knife. The scalpel blade is the cheapest instrument in the operating room and fresh blades should therefore be

used liberally. Atraumatic dissection is a largely acquired skill but obeys a few guiding principles. Tissue planes are always present and should be followed when possible. This allows for a rapid and precise dissection, following the naturally present tissue planes. When this plane is entered, it opens up and can be easily followed with good traction and counter-traction. Blood staining makes the identification of tissues more difficult and must be prevented. Blunt dissection can be considered an atraumatic technique when following the tissue planes. However, uncoordinated and aggressive spreading with scissors or a vascular clamp is usually indicative of lack of anatomical knowledge on the part of the surgeon, and leads to more bleeding and crush-avulsive tissue trauma.

Tissue desiccation must be prevented at all cost. Dry tissue is dead tissue. The operating room lights expedite this process because they act as a heat source. Lengthy procedures are at higher risk for tissue desiccation. Certain tissues such as tendon, nerves, blood vessels and bone are also at higher risk. The paratenon dries within seconds of air exposure. It is critical to moisten the tissues intermittently. The more practical solution for lengthy cases is the placement of saline-moistened sponges onto the tissues. This cannot be overemphasized.

Skin Closure

In animal surgery, skin closure is as important as it is in clinical surgery. If the skin edges are not precisely aligned at the end of the procedure, delayed wound healing can occur, with the high likelihood of wound separation, colonization and infection. Wound margin eversion will ensure uninterrupted healing and can be simply achieved with careful technique.

Planning

A well-conceived operation will ensure ease of execution. This pertains to all aspects of the procedure, including good lighting (which is often lacking), and operating theatre ergonomics (surgeon fatigue is directly correlated with the quality of the work delivered). Probably the most important point is not to compromise with any of the steps of the operation. When one compromises with the lighting for instance, then one compromises with a dull blade, poor instruments, uncomfortable posture, one thing after the next leading to fatigue, frustration and failure. Furthermore, in animal studies, often the same procedure is performed a number of times in repetition. Meticulous and standardized technique will provide reproducible and more consistent data.

CONCLUSION

Wound healing is a necessary prerequisite in all experimental surgery, whether or not it is wound healing itself that is being studied. Wound healing is broken down into various phases but in reality they overlap: hemostasis, inflammation, proliferation and remodeling. Each phase is characterized by up and down regulation of specific processes, in turn driven by chemokines that originate both from the repair tissue itself as well as the adjacent wound bed.

Vascularization and oxygenation are rate-limiting factors which are at the core of all wound healing. Despite certain advantages of small mammalian animal models, the swine model is best suited for wound healing *in-vivo* studies, albeit at higher cost and logistical effort. Atraumatic tissue handling will ensure minimal tissue injury and uninterrupted healing in all experimental surgery procedures.

ABSTRACT

Organ transplantation has become a preferred clinical therapy for end-stage organ disease. Since the first kidney transplant was successfully performed in 1954, organ transplantation developed rapidly and more methods for transplantation have quickly emerged. Therefore, based on this background, the method with which to preserve organs for a long time and the ideal method for organ preservation could become meaningful problems that require discussion by specialists and doctors. In this chapter, we discuss the addition of materials in preservation solutions, list the main preservation solutions, and describe gene therapy in organ preservation and clinical trials. Some classic preservation solutions are still used in clinical works, such as University of Wisconsin solution and Histidine-tryptophan-ketoglutarate solution; however, others are mainly based on these classic solutions with the addition of some materials. Recent studies have found that new materials such as gas molecules added into a solution can provide better protection for organ preservation, and we are glad to see more studies about how to better preserve donor organs even while machine preservation appears to be most prominent.

ABBREVIATIONS

BNP-1	bovine neutrophil peptide-1
CO-RMs	carbon monoxide release molecules
DGF	delayed graft function
EC	Euro-Collins
EGF	epidermal growth factor
HC-A	hyperosmolar citrate adenine
HES	hydroxy-ethyl starch
HOC	Hypertonic citrate
HTK	Histidine-tryptophan-ketoglutarate
IGF-1	insulin-like growth factor-1
IGL-1	Institute George-Lopez
LPD	low-potassium dextran
MDA	malondialdehyde
NGF	nerve growth factor
PBS	Phosphate-buffered sucrose
PEG	polyethylene glycol
PGD	primary graft dysfunction
PKR	protein kinase.
PRRs	pattern recognition receptors
RIG1	retinoic acid inducible gene 1
ROS	reactive oxygen species
SCOT	Solution de conservation des organes et des tissus
siRNA	small interfering RNA
SMO	shanghai multi-organ preservation
SP	substance P
UW solution	University of Wisconsin solution

1. INTRODUCTION

With the development of organ transplantation, solid organ preservation has become a significant focus in the transplantation field. Considerable attention is given to the *ex vivo* period as this segment represents a vulnerable timeframe whereby organs are susceptible to ongoing cellular damage that is further compounded by reperfusion injury upon re-anastomosis (Korte 2016). In the late 1960s, two important studies demonstrated that kidneys could be safely preserved for 30 hours by cold storage and for as long as 72 hours by continuous perfusion. With this evidence, some experts considered hypothermia, which can be utilized to decrease the metabolic activity of donor organs during the *ex vivo* period. However, hypothermia is unable to abolish all cellular damage, as metabolism persists at approximately 5–10% of normal levels. In addition, hypothermia can lead to Na⁺/K⁺-ATPase alterations, ATP depletion, the dysregulation of Ca²⁺ homeostasis, mitochondrial perturbations, xanthine oxidase accumulation, and increased levels of reactive oxygen species (ROS), which may have deleterious effects on cellular viability. Therefore, preservation

solutions have been implemented in conjunction with hypothermia for additional cellular protection. In 1988, Belzer et al. presented the opinions that proper solid organ storage solution should obey the following principles: (1) minimize hypothermic-induced cell swelling; (2) prevent intracellular acidosis; (3) prevent the expansion of the interstitial space during the flush-out period; (4) prevent injury from oxygen-free radicals (especially during reperfusion); and (5) provide substrates for regenerating high-energy phosphate compounds during reperfusion (Belzer and Southard 1988). According to these principles, numerous solutions are commercially available while others remain institutionally derived.

2. HISTORY OF PRESERVATION SOLUTIONS

Kidney transplantation remains limited by four problems: (1) a high rate of delayed graft function; (2) early loss of kidneys from chronic rejection; (3) donor kidney shortages; and (4) the need for immunomodulation treatments. However, improved cold storage methods can significantly impact the first 3 of these 4 major problems, so the development of new types of organ preservation solutions can be a new strategy for organ transplantation. After the introduction of static Collins solution by Collins in 1969, prolonged kidney preservation became feasible. Currently, the principle solutions for kidney preservation are University of Wisconsin (UW) solution, Histidine-tryptophan-ketoglutarate (HTK) solution, Celsior solution, Institute George-Lopez (IGL-1) solution, Polysol solution, Euro-Collins solution, hypertonic citrate (HOC) or Marshall solution, and Phosphate-buffered sucrose (PBS). Considering their electrolyte composition, these solutions are divided into intracellular-type and extracellular-type. Intracellular solutions are characterized by high potassium and low sodium concentrations, which is necessary to prevent cell swelling. Because the Na^+/K^+ -ATPase is inactive during cold storage, a solution in the extracellular space with an Na^+/K^+ balance equal to the intracellular compartment reaches Donnan equilibrium, preventing sodium and chloride from entering the cell. Intracellular-type solutions such as UW are considered important to preserve cell viability. The extracellular-type of solution, such as HTK, has low potassium and high sodium concentrations. Recent studies have suggested that this composition is equal to, or even better than, the intracellular type, as potassium can induce vasospasm.

3. THE IMPROVEMENT OF PRESERVATION SOLUTIONS BY ADDING MATERIALS

Growth Factors

Growth factors are cytokines that can stimulate cell growth. MeAnuhy et al. found that when a variety of growth factors were mixed into the UW solution, such as an antimicrobial peptide (bovine neutrophil peptide-1, BNP-1, also referred to as bactenecin), a neuropeptide (substance P, SP), a neurotrophin (nerve growth factor, NGF), and two polypeptide growth factors (epidermal growth factor (EGF) and insulin-like growth factor-1, IGF-1), dog kidneys were successfully preserved for 6 days. The serum creatinine level was lower in the normal

UW solution group than in the normal group 3 days after storage for 4 days, and the canine kidney function for 6 days was the same as that of the normal group (McAnulty 2002). Another animal experiment showed that the addition of growth factor and FRL67653 (a P38 mitogen-activated protein kinase inhibitor) to the UW solution significantly improved the preservation of a pig kidney, reduced ischemia-reperfusion injury, and reduced the incidence of long-term renal fibrosis and infection (Desurmont 2011). These studies suggest that the addition of growth factors to the organ preservation solution can improve the effect of simple cryopreservation of organs; further research is needed to explore potential applications.

Trimetazidine

Trimetazidine can enhance myocardial oxygen supplementation, maintain mitochondrial function and reduce vascular resistance and is mainly used in the clinical treatment of angina. In a study of acute coronary ischemia, trimetazidine was shown to protect mitochondrial structures and improve mitochondrial function via enhanced oxidative phosphorylation and a reduction in the production of reactive oxygen species. Faure et al. evaluated the mitochondrial protective effects of trimetazidine added to UW liquid and Celsior solution and showed that pig kidneys were saved at low temperature for more than 72 hours (Faure 2003). Belous et al. also found that hypothermia, especially combined with an elevated extracellular calcium concentration, would significantly increase mitochondrial calcium intake, and the increased calcium concentration would eventually lead to the irreversible damage of mitochondrial structure and function (Belous 2003). Mitochondrial damage is closely related to acute rejection, which is induced by ischemia reperfusion and could cause delayed graft function (DGF) and chronic graft rejection. Thus, the protective effect of trimetazidine in reducing mitochondrial damage might be the main mechanism by which ischemia reperfusion injuries are decreased. However, some studies found opposite results, suggesting that the role of trimetazidine in reducing ischemia reperfusion injury is not obvious (Abreu Lde 2011). Therefore, the use of trimetazidine in organ preservation solution still needs further study.

Thrombin Inhibitors

Recently, studies have shown that adding Melagatran, a type of thrombin inhibitor, to the UW solution can improve the recovery of renal function after ischemia reperfusion in porcine kidneys. Compared with the control group, the survival rate of the experimental group was significantly improved at 7 days after the operation, and kidney damage and the inflammatory response were significantly reduced (Giraud 2009). Moreover, the addition of a thrombin inhibitor to the preservation solution can prevent the occurrence of chronic diseases such as renal interstitial fibrosis, tubular atrophy and infection.

Small Interfering RNA (siRNA)

RNA interference is a way to down-regulate specific proteins by limiting gene expression and siRNA is one of the common tools. It has been demonstrated that cysteine-aspartate 3

(caspase-3) siRNA can be directly added to HOC solution for the preservation of porcine kidney, which can reduce the level of caspase-3 and cell death, improve kidney oxygenation and acid-base balance, thereby reducing ischemia-reperfusion injury (Yang 2011; Hosgood 2011; Nicholson 2011). The main challenge of applying siRNA to preservation solution is its safety, which includes the choice of vector, ectopic expression of the transgene, and the adverse effects of gene expression.

Polyethylene Glycol

Polyethylene glycol (PEG) was able to reduce the hypoxic ischemic injury of renal tubular cells. Hauet et al. added 30 g/L polyethylene glycol (20000 U) to UW solution and high sodium UW solution and found that the renal tubules in the PEG group were significantly smaller than renal tubules that had been maintained in the UW solution alone in porcine autologous kidney transplantation model 7 days after the operation (Hauet 2002).

Calcium Channel Blockers

Organ preservation can be regarded as a mitochondrial function protectant. Mitochondria produce ATP and maintain the intracellular calcium balance, and mitochondrial calcium overload is a characteristic change during ischemia reperfusion injury. Calcium channel blockers such as nitrendipine can inhibit ischemia reperfusion injury and improve the effect of cryopreservation (Sasaki 1999).

Fluorocarbon (Peflanca)

The capacity of Fluorocarbon dissolved oxygen is 20 to 25 times higher in the plasma, and the oxygen saturation curve also shows that low temperature is conducive to the release of oxygen. Studies found that the addition of fluorocarbon to UW solution can increase organ oxygen supplementation and improve the level of oxidative phosphorylation during cryopreservation. During pancreas preservation, the fully oxidized fluorocarbon can maintain the preservation solution at approximately 85% oxygen saturation for more than 18 hours. Compared with the UW solution, this method can increase the recovery of islet function and improve the effect of pancreas transplantation.

Gas Molecules

Recently, gas molecules have become a focus in organ preservation. In addition to traditional oxygen, the effects of gasses such as hydrogen, nitric oxide, hydrogen sulfide and carbon monoxide, on reducing ischemia reperfusion injury and the potential mechanisms involved have been explored. Among these findings, carbon monoxide release molecules (CO-RMs) have received more attention. The molecule is a transition metal carbonyl

compound that can control the release of carbon monoxide into tissues. A recent study confirmed that the addition of CO-RMs to the preservation solutions can significantly reduce renal, liver and heart ischemia reperfusion injury. Gas molecules will have broad clinical prospects for the protection of transplanted organs (Wei 2010; Soni 2012; Jain 2012; Mehta 2012).

Chinese Medicine Ingredients

Recently, Chinese researchers added some traditional Chinese medicine ingredients to organ preservation solution and achieved encouraging results. Wang et al. used *Salvia miltiorrhiza* irrigation in a rat pancreas-duodenal kidney transplantation model and found that the levels of serum amylase, serum creatinine and serum malondialdehyde (MDA) in the treatment group were significantly lower than in the control group, and the pathological damage of the pancreas and kidney was also reduced after transplantation. That is because *Salvia miltiorrhiza* scavenges oxygen free radicals and protects against ischemia-reperfusion injury. Zhou et al. used ginseng extract in the HC-A kidney preservation solution for cryopreserved isolated canine kidneys, and the results showed that, compared with the control group, ultrastructural tissue damage was significantly reduced in the treatment group, and serum creatinine was significantly decreased, suggesting that ginseng extract can help reduce renal ischemia reperfusion injury. Another study also confirmed that Astragalus, dodder, oxymatrine and other traditional Chinese medicines can reduce of ischemia- reperfusion injury, suggesting that the addition of some traditional Chinese medicine ingredients to the organ preservation solution can improve the effect of existing preservation solutions. Chinese medicine has already shown advantages and is expected to become a field of study for organ preservation materials.

4. MAIN PRESERVATION SOLUTIONS

General without Organ Specificity

University of Wisconsin Solution

In 1988, Belzer et al. developed an excellent organ preservation solution at Wisconsin University named UW solution (University of Wisconsin), which has become the gold standard among organ preservation solutions (Belzer and Southard 1988). UW solution combines metabolically inert substrates, such as lactobionate and raffinose, with hydroxyethyl starch (HES) as a colloid, an ATP precursor (adenosine) and oxygen radical scavengers (glutathione and allopurinol). The principal benefit of this solution is that it is associated with good outcomes of short and long term kidney preservation. Its disadvantages are due to the high viscosity, which compromises the microcirculation, and the high potassium concentration that can produce vasoconstriction with hyperaggregation of HES. Two kinds of UW solution have been utilized for HMP and CS. In CS, UW-CSS is the main solution, while UW-G is used for HMP. Lactobionate is replaced by gluconate and the potassium level is

reduced in UW-G, resulting in a consistency that more closely resembles an extracellular solution (Catena 2013).

Histidine-Tryptophan-Ketoglutarate Solution

HTK was introduced in 1980 by Bretschneider and was originally used as a cardioplegic solution (Yuan 2010). HTK contains histidine and tryptophan as membrane stabilizers as well as antioxidants and ketoglutarate for anaerobic metabolism. HTK studies have shown conflicting results. However, its low viscosity may improve microperfusion. Because of this characteristic, HTK is recommended in HMP at low pressures and high perfusion volumes (Yuan 2010; Catena 2013).

Celsior Solution

Celsior solution is a colloid that was developed in 1994 and was originally used in heart transplantation before being extended to other abdominal organs. It combines the osmotic efficacy of UW (lactobionate and mannitol) with the potent buffering ability of HTK (histidine) (Yuan 2010). Colloid solutions contain added macromolecules that do not pass the cellular membrane and thus prevent tissue edema caused by the hydrostatic pressure of HMP (Catena 2013).

Institute-George-Lopez

IGL-1, a fairly new preservation solution developed in France (Faure 2003), combines the advantages of UW and Celsior (Yuan 2010). Polyethylene glycol is bound to cell and tissue surfaces, thus stabilizing them from adverse interactions. Studies suggest that this feature modifies the inherent immunogenicity of donor tissue as a consequence of ischemia-reperfusion injury (Eugene 2004). Badet et al. demonstrated a reduced incidence of delayed graft function (DGF) compared with kidneys preserved with UW. However, a recently published multi-center study showed no significant difference in DGF when IGL-1 was compared with UW (Badet 2005; Catena 2013; Codas 2009).

Polysol

Polysol was recently introduced with the goal of facilitating the transplantation of ischemically damaged organs (Yuan 2010). Therefore, amino acids, vitamins, potent buffers, and antioxidants have been added to support metabolism under hypothermic conditions. The solution has also been tested during HMP (Bessems 2005). A case study by Schreinemachers et al. demonstrated superior graft survival with Polysol compared with UW in a porcine renal autotransplant model (Schreinemachers 2009; Doorschodt 2009; Florquin 2009; van den Bergh 2009; Weerman 2009). Further reports by the same group have shown beneficial effects of Polysol for kidneys damaged by warm ischemia (Schreinemachers, Doorschodt, Florquin, Idu, et al. 2009). Polysol is currently used in experimental trials only. While recent reports on Polysol appear to be promising, more clinical data are necessary to evaluate its efficacy and benefits (Bessems 2005; Catena 2013).

Hypertonic Citrate

HOC, or Marshall's solution, an intracellular-mimicking medium, is extensively used for clinical transplantation in the United Kingdom and Australia (Wilson 2007). HOC uses

mannitol as the impermeable solute and citrate as its buffer to aid calcium extension from the cell while maintaining a physiologic pH. As a hypertonic solution, HOC prevents the entry of fluid into cells. Experimental trials using canine kidneys have demonstrated it to be effective for preservation periods of up to 72 hours (Kay 2009; Catena 2013).

Lifor Solution

Lifor solution is a type of anti-extracellular organ preservation solution developed on the basis of the comprehensive analysis of UW solution. It has low viscosity, low osmotic pressure, is rich in ATP and other nutrients, and the formula is simple and inexpensive. In 2007, Stowe et al. reported for the first time that Lifor preservation solution was used to preserve an isolated pig heart (Stowe 2007). Recently, a series of studies have shown that Lifor solution is superior to UW solution in reducing renal ischemia-reperfusion injury, alleviating cell apoptosis and improving renal blood flow and renal vascular resistance (Gage 2009; Regner 2010). In preserving small intestine, the effect is similar to UW solution, but the cost is low. However, Lifor solution is still in the experimental stage, and its effects need to be further evaluated.

Kyoto Solution

Kyoto solution is a type of extracorporeal multi-organ preservation solution that was developed by Kyoto University in Japan; it was initially used as a lung preservation solution (Chen 2004; Nakamura 2004; Wada 2004). The preservation solution uses trehalose and gluconic acid as non-permeable molecules, effectively reducing cell edema, which can replace the kapok and lactose acid in UW solution, but at a lower cost. Until now, the preservation solution has been used for clinical lung and kidney preservation and has shown benefits over UW solution (Chen 2004; Yoshida 2002). However, the use of Kyoto solution in liver, pancreas and small intestine preservation is still under research (Zhao 2008).

Solution De Conservation Des Organes Et Des Tissus

Solution de conservation des organes et des tissus (SCOT) is a multi-organ preservation solution developed by the University of Poitiers, France, with high sodium ion and low potassium ion concentration, which uses PEG 20 kDa (19 842 U, 30 g/L) as a colloidal component of the preservation solution. Animal experiments showed that the preservation effect in the kidney, liver and islet transplantation are better than with UW solution; therefore, it has been used in clinical kidney preservation (Billault 2006).

Shanghai Multi-Organ Preservation Solution

With the rapid development of organ transplantation in China, multiple organ transplantation has become increasingly common. Although simple solutions are still advantageous for domestic transplantations, high prices have become a huge problem. Some researchers invented a new kind of solution named shanghai multi-organ preservation (SMO) solution, which is based on UW solution. SMO solution uses Xylitol as energy and ligustrazine as an oxygen scavenger. In animal models, SMO showed significant protective function in the liver and kidney compared to HTK, and the effect was the same as UW.

Kidney Preservation Solutions

Collins Solution

Collins solution was designed in the 1960s and was considered the preservation solution of choice for more than 15 years until organ preservation was revolutionized by the introduction of UW solution in 1988 (Latchana 2014). Collins solution is a high potassium, high magnesium, low sodium intracellular liquid type solution. By maintaining glucose concentration at 420 mol/L, Collins used this liquid to successfully save the kidneys for 30 hours at 4°C, and after transplantation, the kidneys showed good function. In 1976, the European Transplantation Organization improved Collins solution and removed the negative effects of magnesium ions, forming the Euro-Collins (EC) solution. They recommended the solution as a standard preservation solution for clinical kidney transplantation. Thus, EC solution was widely used in Europe (de Boer 1999).

Hyperosmolar Citrate Adenine Solution

Hyperosmolar citrate adenine (HC-A) solution, also known as hypertonic citrate adenine solution, was jointly developed by the Second Military Medical University Changzheng Hospital and Shanghai Blood Center in 1979. Its main components are potassium, sodium, magnesium sulfate, citrate, mannitol and adenine. HC-A solution is the main irrigation and cryopreservation solution for organ transplantation in China. It has a simple preparation, good stability, and low price. Currently, the utility of HC-A solution has been widely affirmed after 20 years of use.

HCA-II Solution

HC-A solution has been used for more than 20 years. With the further study of preservation, the inadequacies in this solution have gradually appeared. In recent years, combined with the latest organ preservation theory, the HC-A preservation formula has undergone comprehensive improvement. In accordance with the preservation of the composition of the elements, a phosphate buffer system has been added, and a cell membrane protective agent and the antioxidant ligustrazine have been incorporated, which increased energy substrate content and osmotic pressure. HCA-II organ preservation solution was developed after animal experiments and a number of clinical applications in the transplant center confirmed that HCA-II preservation solution was significantly better than HC-A liquid for kidney preservation. Compared with the HTK solution, kidneys could be saved for 36 h, 48 h and 72 h. After 72 h, the apoptotic index was significantly lower in kidney tissue that had been stored in HCA-II solution compared to kidney tissue that had been stored in HTK solution. The results of an animal model of canine kidney transplantation showed that the preservation effect was better than that of HTK and was equivalent to that of UW preservation solution. HC is the upgraded liquid product. And the product has a national patent and is expected to officially enter production in 2007.

Heart Preservation Solutions

According to the systematic review of Demmy et al. as many as 167 HPSs were used for heart preservation in the USA in the middle of the 1990s. At present, the histidine-tryptophan-ketoglutarate (HTK) solution, the University of Wisconsin (UW) solution and the Celsior solution are most commonly used for heart preservation.

HTK (or Custodiol) was introduced by Bretschneider in the 1970s as a cardioplegic solution and has subsequently been used in organ preservation for the heart, liver and pancreas. Its usage has been increasingly popular in cardiac surgery because a single administration of cold HTK in the coronary vascular bed provides reliable protection from IRI for at least 2 h.

The Euro-Collins solution is an intracellular HPS with high concentrations of glucose (194 mmol/l) and K^+ (115 mmol/l) that includes bicarbonate and phosphate buffer systems. The Stanford solution is similar to Euro-Collins with the exception of an even higher glucose level (250 mmol/l) and a lower K^+ concentration (27 mmol/l).

The UW solution, developed by Belzer et al. typically has a low Na^+ concentration, although an extracellular modification of this HPS that includes 125 mmol/l Na^+ also exists. Along with intracellular-type HPSs, there are several widely accepted extracellular solutions with high Na^+ and low K^+ concentrations.

The most common extracellular HPS is Celsior. Celsior is enriched with the reactive oxygen species scavengers lactobionate and glutathione, which ensures the prevention of oxidative stress during reperfusion. In contrast to other HPSs, Celsior contains 20 mmol/l glutamate, which has anti-ischemic activity and exerts cardio-protective effects. In addition, Celsior, HTK and the Stanford solution contain the polyatomic alcohol mannitol, which can prevent edema and quench reactive oxygen species (Minasian 2015).

However, the high molecular weight compounds within UW, such as hydroxyethyl starch (HES), result in a highly viscous solution that has been implicated, in part, in organ dysfunction, thereby supporting the development of less viscous alternatives, including Celsior (CEL) and histidine- tryptophan-ketoglutarate (HTK).

Many targeted approaches to cardiac organ preservation have been attempted, including the development of Plegisol, which arose from the initial St. Thomas solution used for cardioplegia, albeit with slight modifications, including the addition of a buffering system. In contrast to the aforementioned acellular approaches, Papworth solution was centered on the inclusion of donor blood in its composition. The different metabolic demand and physiology of the lung supported the construction of pulmonary specific solutions, including Perfadex (PER), which has been authorized to be used in pulmonary transplantations by the Food and Drug Administration (FDA) in the United States (Latchana 2014).

Liver Preservation Solutions

Preservation solutions for donor liver are required to preserve homeostasis, support liver metabolism and delay cell damage. Several solutions are currently available: University of Wisconsin (UW), Histidine-Tryptophan-Ketoglutarate (HTK), Celsior (CS) and the most recent Institute Georges Lopez-1 (IGL-1). They all differ in terms of composition, ion balance, viscosity, osmolality and cost.

UW is a high viscosity colloid solution due to the presence of hydroxyethyl starch (HES), high potassium and low sodium concentrations (125 mmol/l and 27 mmol/l, respectively). Despite its widespread use, UW carries some side effects: high viscosity might result in impaired flushing with microcirculatory disturbances; high potassium concentration might provoke cardiac arrest in the recipient upon liver reperfusion; and finally, ischemic-type biliary lesions are not rare.

HTK represents an alternative to UW and possesses advantages that can be summarized as lower viscosity, lower potassium content (10 mmol/l, thus avoiding the risk of hyperkalemia) and better buffering properties. HTK was believed equivalent to UW for SCS but less expensive; however, recent findings highlighted HTK-associated disadvantages. In a large single-center series and a retrospective analysis of the UNOS database, the survival of grafts from standard or ECD donors did not differ when grafts were preserved with HTK or UW; however, in subgroup analyses, HTK-preserved grafts achieved significantly inferior survival after exposure to long-lasting cold ischemia or procurement from DCD donors. Furthermore, two different clinical trials from Meine et al. and Gelsen et al. reported relevant increases in the incidence of NAS in patients receiving grafts from DCD donors preserved with HTK. The reason that HTK is associated with worse outcomes after LT is not fully understood; the lack of antioxidants and oncotic agents might be an explanation. To summarize, the available evidence points towards the avoidance of HTK as a preservation solution for livers.

Celsior solution has low viscosity, high sodium and low potassium concentration (100 mmol/l and 15 mmol/l, respectively) and combines the best aspects of both UW and HTK. It retains the buffering properties of HTK (histidine) and the presence of impermeants as in UW (lactobionic acid).

Sodium and potassium concentrations in IGL-1 are switched compared to UW ($[Na^+] = 120$ mmol/l, $[K^+] = 25$ mmol/l) and HES is replaced by polyethylene glycol, resulting in lower viscosity. These properties could improve liver wash-out during procurement and reduce IRI. IGL-1 has been previously tested in a rat model of isolated liver perfusion and in a pig model of auto-transplantation, showing better preservation of cell integrity. Dondero et al., in a recent randomized trial that included fatty livers, failed to demonstrate the superiority of IGL-1 and found that it is at least as effective as UW and is less expensive. However, the outcome of steatotic donor grafts was not the primary endpoint of this study, which was probably underpowered to draw solid conclusions. Randomized clinical trials comparing IGL-1 to other preservation solutions are still missing, but the recent large series analysis from Adam et al. confirmed good outcomes and postulated possible advantages for IGL-1. Further investigation is therefore needed to confirm this hypothesis.

Identifying the best preservation solution is a difficult task since randomized trials have shown conflicting results; however, some conclusions can be drawn from large studies or clustering data from different trials. In a recent meta-analysis, Zuluaga et al. reported no differences in LT outcomes when UW was compared to CS or HTK. In particular, no differences were observed in terms of EAD, 1-year patient survival and the occurrence of NAS. Adam et al. partly confirmed this observation in their recent retrospective analysis of the European Liver Transplant Registry that included more than 48,000 LTs. Grafts preserved with UW, IGL-1 or CS showed similar 3-year graft survival; however, IGL-1 was associated with a better preservation of partial liver grafts as shown by higher graft survival in this group. Notably, grafts preserved with HTK exhibited significantly inferior survival three

years post-LT when compared to grafts preserved with other preservation solutions, and based on multivariate analysis, HTK was an independent risk factor for graft loss.

All available preservation solutions were developed with the purpose of preventing hepatocyte death during the ischemic storage phase. Other cell populations, including cholangiocytes, are probably not so well protected from IRI. Two recent studies that focused on the pathological aspects of the common bile duct have revealed that the bile duct epithelium is seriously injured at the end of SCS in up to 88% of cases. These findings indicate that the bile duct of almost all grafts suffers relevant injury, which might be responsible for NAS development. These complications add relevant morbidity and significantly reduce long-term graft survival, representing a rising concern due to the increased transplantation of DCD grafts, which is associated with markedly higher rates of biliary complications. Improved bile duct preservation might be offered by MP, which has been associated with better preservation of the bile duct in experimental settings (Gilbo 2016).

Pancreas Preservation Solutions

Islets are most often infused into the patient with an open laparotomy incision immediately after processing while the patient is still in the operating room. Alternatively, islets may be cultured and infused postoperatively via a percutaneous approach. Islets are infused into the portal system using a stump of the splenic vein, via direct puncture of the portal, or by cannulation of the umbilical vein. With a significant tissue volume infused into the portal vein, the elevation of portal pressure may lead to a reduction in blood flow and portal vein thrombosis. Because of this risk, heparin anticoagulation is recommended. Portal pressure is monitored closely during islet infusion and should not exceed 25–27 cm H₂O (18.4–20 mm Hg). When pellet volume is <20 mL and the liver is healthy, portal pressure usually does not increase substantially. If portal pressure does increase during the infusion of a large volume of unpurified islets, portal infusion should be discontinued and the remaining islets should be dispersed into the peritoneal cavity or injected into the leaves of the mesentery or omentum, bowel subserosa, gastric submucosa, or intra-muscular space. Although islets transplanted into these alternative sites have been shown to survive in animal models, whether this approach is effective in the clinical setting is unknown (Witkowski 2014; Savari 2014; Matthews 2014).

Only a few studies have adequately evaluated lower temperature conditions in islet culture/preservation before our report. Frankel et al. reported the comparison of 8°C storage with 22°C storage or 37°C culture for 1 week using islets from obese (ob/ob) mice. They showed that the glucose-stimulated insulin release was better maintained by storage at 8°C in tissue culture medium with a high concentration (18 mM) of glucose and an additional pre-incubation period of 4 h at 37°C than by storage at 22°C or 37°C. In addition, 8°C storage in a high-potassium “intracellular medium” resulted in a better subsequent glucose-stimulated insulin release and islet morphology in comparison to a 37°C culture in traditional culture medium. Korbitt et al. reported the survival of rat pancreatic b-cells after 96 h of storage at 4°C. After 4°C storage in Collins solution with albumin and benzamidine, b-cells exhibited a higher insulin content than after culture in HAM’s F10 at 20°C or 37°C, although their capacity for subsequent insulin synthesis and release was comparable. It was demonstrated

that storage with UW solution plus pefabloc at 4°C was superior to culture at 20°C or 37°C; however, the experiments used unpurified islets (Noguchi 2015).

The first step after surgical dissection is to flush the extracted pancreas with a chilled preservation solution. This is usually done with University of Wisconsin (UW) solution. UW solution gives equivalent or superior results to other perfusions in many but not all studies by preventing the loss of amylase and inducing a slight shrinkage of the acinar cells, which in turn improves the density separation of islets and the viability of the cells. Other preservation solutions include Celsior, HTK, IGL-1 and others. The flushing step cools the pancreas and removes debris and thrombi.

Cold storage and transport of the pancreas is vital to islet yield and viability; warm ischemia has been found to damage tissue; however, cold ischemia time beyond 8 h also results in reduced yields and a lower quality of human islets. In most studies, shorter cold ischemic time is associated with better islet yields. Transport using a two-layer method where the pancreas rests on a substrate in the top layer of a perfluorocarbon “bath” appears to give slightly improved outcomes and showed promising results in pancreas tissues from humans (Deters 2011; Stokes 2011; Gunton 2011).

Lung Preservation Solutions

The procurement of lungs for transplantation is a challenging task since lung tissue is at a high risk of ischemic and hypoxic injuries, which can result in life-threatening primary graft dysfunction (PGD). During the first successful LTx surgeries, cooling was the only technique of preservation. The application of various organ preservation solutions emerged over the following decades. To extend the cold ischemic time, intracellular-type solutions such as Euro-Collins or University of Wisconsin solution were used when available. As understanding of the pathological and pharmaceutical pathways of lung preservation developed, practice shifted towards extracellular-type preservation solutions, primarily the low-potassium dextran (LPD) solution. The LPD solution is understood to work via the following two mechanisms: the low-potassium concentration maintains a low pulmonary artery (PA) pressure during perfusion and the dextran acts as an oncotic agent, increasing the intravascular pressure to prevent interstitial lung edema.

There are distinct advantages to using an extracellular-type LPD solution in lung procurement. LPD is the accepted standard pulmoplegic solution and shows superior preservation effects. In addition to potassium and dextran, other pharmaceutical agents are currently used in cold ischemic lung procurement, such as prostaglandins and/or methylprednisolone to prevent vasoconstriction (due to the cold flush) and inflammatory responses (Andreasson 2014; Dark 2014; Fisher 2014).

5. GENE THERAPY IN ORGAN PRESERVATION

RNA interference (RNAi) is a highly conserved biological phenomenon in all eukaryotes, including renal cells. In the late 1990s, due to the development of molecular biology and genetics, the biological understanding of RNA evolved from simply an intermediate between

DNA and protein to a dynamic and versatile regulator that functions in genes and cells in all living organisms. In 1998, as a milestone, Fire et al. injected a few molecules of double-stranded RNA (dsRNA) into *Caenorhabditis elegans* and found that dsRNAs could specifically interfere with the protein expression of an endogenous gene. This molecule was named small interfering RNA (siRNA) and mediates RNAi. siRNA is able to recognize and degrade homologous host mRNA. Therefore, the gene from which the mRNA is transcribed is silenced, which is referred to post-transcriptional gene silencing.

Although RNAi exists naturally, synthetic artificial siRNA exerts similar effects as natural endogenous micro-RNA (miRNA). Both sense and antisense strands of siRNA can be synthesized separately and annealed to form double-stranded siRNA duplexes *in vitro*. After the siRNA is delivered into the cytoplasm, the artificial siRNA silences the target gene using similar biological processes as endogenous miRNA. Since the introduction of 21-nucleotide artificial siRNAs that can trigger gene silencing in mammalian cells, synthetic siRNA has generated much interest in biomedical research, including in the kidney. siRNA as a strategic molecule has been expected to impact the field of innovative therapy. Because siRNA is highly efficient at gene silencing, it is possible to develop specific siRNA-based drugs that could target any genes, including those that have no known pharmacological antagonists or inhibitors. Different types of synthetic siRNA have been tested for their efficacy in various disease models, including cancer, autoimmune disorders, cardiovascular injuries, and organ transplantation, including native and transplanted organ injuries.

In addition to the *in vitro* delivery of siRNA, *ex vivo*/*in vivo* siRNA delivery to target organs is an indispensable step before its clinical application. If it was directly delivered into the kidneys, siRNA could obtain higher local concentrations, which would result in improved gene silencing efficacy. During kidney transplantation, *ex vivo* local delivery of siRNA into the donor kidney is feasible because it could be facilitated by the unique structure of the kidney and the characteristics of kidney transplantation. Recently, we utilized an *ex vivo* isolated porcine kidney reperfusion system to assess the efficacy of naked caspase-3 siRNA. The caspase-3 siRNA was directly infused into the renal artery (locally) and autologous blood perfusate (mimic systemic delivery) before 24-hour cold storage (CS), followed by an additional reperfusion for 3 hours. The results demonstrated that the caspase-3 siRNA improved ischemic re-perfusion (IR) injury with reduced caspase-3 expression and apoptosis, better renal oxygenation and acid–base homeostasis (Yang 2013; Jia 2013). These promising proof-of-principle observations provide valuable guidance for the further development of siRNA in clinical practice.

Cold ischemia injury activates multiple signaling pathways and upregulates several genes, subsequently causing cell apoptosis and death and resulting in organ damage. In addition to single siRNA delivery, siRNA cocktails have been used for better efficacy to silence multiple genes. Recently, Min's group demonstrated that the perfusion and preservation of donor hearts with siRNA solution can attenuate cold I/R injury during heart transplantation, and an siRNA cocktail that contains 3 siRNAs that target C3, RelB, and TNF α showed a synergistic protective effect compared with single siRNAs (Zheng et al. 2009). Based on their previous study, the authors further reported that treatment with siRNA targeting the C3, Fas, and RelB genes successfully attenuated I/R injury and improved renal graft function in a murine kidney transplantation model (Zheng 2016). MMPs also play an important role in injury to the transplanted kidney. MMP expression is increased in patients with chronic antibody-mediated rejection, and because of the role of MMPs in fibrotic renal

diseases, MMPs have been suggested as a possible common pathway for chronic allograft nephropathy in the transplanted kidney (Yan 2012). In a rat kidney cold perfusion model, the inhibition of MMP-2 during perfusion via MMP-2 siRNA led to a decrease in MMP-2 levels in the perfusate, as well as a decrease in LDH, NGAL, and CcO release after 22 hours of perfusion (Moser 2016).

Long-term pancreatic cold ischemia contributes to decreased islet number and viability after isolation and culture, leading to poor islet transplantation outcomes in patients with type 1 diabetes. Silencing Bbc3 by transfecting Bbc3 siRNA into islets *in vitro* prior to cold preservation improved post-preservation mitochondrial viability (Omori 2016). In a lung isolated preservation model, isolated lungs were exposed to 6 hours of cold ischemia (4°C), followed by 2 hours of warm (37°C) reperfusion with a solution that contained 10% of fresh whole blood and mechanical ventilation with constant low driving pressure. siRNA that targeted Fas was administered intratracheally, as was control small interfering RNA. The results revealed that silencing Fas gene expression reduced edema formation (bronchoalveolar lavage protein concentration and lung histology) and improved lung compliance (Del Sorbo 2016).

Although siRNA therapy for organ preservation is effective and promising, off-target effects are one of the major obstacles for further clinical translation. The induction of various side effects may be caused by unexpected perturbations between RNAi molecules and cellular components. The off-target effects of siRNA were first reported by Jackson and colleagues in 2003 (Baan 2016). Broadly speaking, off-target effects can be siRNA specific or non-specific. The former is caused by limited siRNA complementarity to non-targeted mRNAs. The latter, resulting in immune- and toxicity-related responses, is due to the construction of the siRNA sequence, its modification or the modification of the delivery vehicle. RNA-sensing pattern recognition receptors (PRRs), localized in endosomes, are the most important components of the innate immune system. The responses of PRRs to siRNAs are either TLR-mediated or non-TLR-mediated. The PRR responses are also associated with siRNA sequence specific side effects and have recently attracted lots of attention from researchers (Kabilova 2012). RNA-sensing TLRs (TLR3 and TLR7) are predominantly located intracellularly and recognize nucleic acids released from invading pathogens. The non-TLR-mediated innate immune responses triggered by siRNA binding are linked to the RNA-regulated expression of protein kinase (PKR) and retinoic acid inducible gene 1 (RIG1), which further induce caspase-3 and NF- κ B expression, respectively. The activation of PRRs generates excessive cytokine release and subsequent inflammation (Robbins 2009; Judge 2009; MacLachlan 2009). Based on this second type of off-target RNAi effects, our group further investigated the mechanism of how short-acting caspase-3 siRNA impaired post-transplanted kidneys. The results suggested that the amplified inflammatory responses in caspase-3 siRNA preserved auto-transplant kidneys were associated with TLR3, TLR7 and PKR activation, which may be due to systemic compensative responses, although persistent actions initiated by short-acting caspase-3 siRNA cannot be completely excluded (Yang 2013; Li 2013). In the future, better siRNA designs will decrease these off-target effects to a minimum and acceptable level.

6. CURRENT CLINICAL TRIALS OF ORGAN PRESERVATION

Twenty-five current clinical trials of organ preservation solutions have already been registered on *clinicaltrials.gov*; 19 of them focus on solid organ transplantation. At the time of writing, 6 trials have been completed and relevant articles were published online. These trials have not focused on changing the recipes or inventing a kind of new solution but have addressed the use of new machines for the preservation of organs, especially marginal organs, which can be more complex. Thus, *clinicaltrials.gov* has published many trials mainly based on machine organ preservation, and several of them are still recruiting participants.

The Clinical Trial of Hydrogen-Rich Celsior Solution Applied in Aging DBD Liver/Kidney Transplantation (HRCSDDBD) was sponsored by Renji Hospital, Shanghai, China, in 2015. This prospective, randomized clinical trial proposes to investigate whether hydrogen-rich Celsior solution improves the quality of aging grafts in liver/kidney transplantation. The study is based on the findings of the protective effects of hydrogen gas, which has been reported to display antioxidant properties and protective effects against organ dysfunction induced by various ischemia reperfusion injuries (Abe 2012; Buchholz 2011).

The Evaluation of a Marine OXYgen Carrier: HEMO2Life® for hypOthermic Kidney Graft preservation, Before Transplantation (OXYOP) study was received on December 22, 2015, provided by University Hospital, Brest. It was an interventional study that aimed to evaluate the use of an oxygen carrier HEMO2Life® as an additive in organ preservation solution in kidney transplantation for patients with end-stage renal disease.

The University of Bologna sponsored a trial about hypothermic oxygenated perfusion versus static cold storage for marginal graft (PIO) in 2017, and it is still recruiting participants. This trial aims to assess the impact of hypothermic oxygenated perfusion (PIO) of marginal human kidney and liver compared with static cold storage (SCS).

7. PERSPECTIVE

Although organ preservation solutions have become quite common, the method with which to protect donor organs can still be a valuable research topic in basic and clinical studies. To date, donor organs are different from those retrieved two decades ago, and new solutions and techniques have developed rapidly. However, due to the shortage of donor organs, just the consideration of new techniques is inadequate, and effective strategies to extend the donor pool are advocated.

CONFLICT OF INTEREST

The authors declare that no conflicts of interest exist.

Worcester, MA, US

ABSTRACT

Ex-vivo machine perfusion is a promising way to better preserve organs prior to transplantation. Since the 1930s, researchers have explored machine perfusion as preservation method, but only recently has interest been renewed in this technology as a means to resuscitate extended criteria donor organs. Hypothermic machine perfusion has become the standard in kidney preservation and has been shown to be superior to simple cold storage in resuscitation of inferior quality organs. Now, new results show that normothermic machine perfusion of the kidney may be a yet more powerful tool in donor organ resuscitation. In livers as well, making machine perfusion technology clinically available holds the promise of expanding the donor pool through more effective preservation of extended criteria donor livers, showing potential in decreasing delayed graft function, primary non-function and biliary strictures, all common failure modes of transplanted extended criteria donor livers. However, the precise settings and clinical role for liver machine perfusion has not yet been established. In research, there are two schools of thought regarding both liver and heart perfusion: normothermic machine perfusion, closely mimicking physiologic conditions, and hypothermic machine perfusion, as a means of resuscitative cold storage. A new compromise has been introduced for liver preservation (and applied to kidney preservation as well) called subnormothermic or rewarming machine perfusion as a method to minimize the ischemia reperfusion injury following cold storage but also replenish energy stores prior to transplantation. In hearts, recent preclinical trials show hypothermic perfusion superior to simple cold storage, but normothermic perfusion has been used to extend the storage time and shows promise in resuscitating hearts donated after cardiac death (DCD). In lung allograft transplantation as well, normothermic machine perfusion offers to increase

function of extended criteria donor grafts and provides a modality for pretransplantation assessment of function. The pancreas shows the highest rate of discard due to unsuitability of any transplanted organ and therefore perhaps stands the most to gain from experimentation in normothermic perfusion as means of extended criteria organ resuscitation.

Keywords: machine perfusion, liver transplantation, heart transplantation, kidney transplantation, lung transplantation, pancreatic transplantation, preservation

ABBREVIATIONS

ATP	adenosine triphosphate
CS	cold storage
DCD	donation after cardiac death
DGF	Delayed graft function
ECD	extended criteria donor
HMP	Hypothermic Machine Perfusion
HOPE	hypothermic oxygenated perfusion
IRI	Ischemia Reperfusion Injury
ITBL	ischemic type biliary lesions
LDH	lactate dehydrogenase
NMP	Normothermic Machine Perfusion
PNF	Primary non-function
RMP	Rearming Machine Perfusion
RV	right ventricle
SCS	simple cold storage
SNMP	Sub-Normothermic Machine perfusion
WI	warm ischemia

INTRODUCTION

The shortage of organ transplantation donors is a worldwide problem. For example, 1,410 patients on the liver transplant waiting list died in 2015. Because of the exponential discrepancy between organ demand and supply, more organs of inferior quality are used every year. However, many of these organs are still discarded. The use of extended criteria donors (ECD) is a promising way to expand the available donor pool. In particular, donation after cardiac death (DCD) liver grafts has become increasingly important as they have become a larger proportion of the donor pool; over 18% of the total donor pool in 2015 (UNOS 2016). DCD kidney grafts are used successfully for clinical transplantation, with outcomes very similar to brain-dead donor grafts, however poorer outcomes have delayed the use of other DCD organs. Due to warm ischemic damage, DCD liver grafts, carry higher risks for delayed graft function (DGF), primary non-function, and biliary complications following transplantation (Saidi 2013). Biliary complications in DCD organs are a major source of morbidity, graft loss, and even mortality long-term after liver transplantation. These

complications are much more common in DCD grafts (20–40% compared to 5% in grafts from brain-dead donors) (Jay 2011). The most troublesome biliary complication is the ischemic-type biliary lesions (ITBL), also called ischemic cholangiopathy.

The risk of ischemic cholangiopathy in grafts from DCD donors is 10 times higher than for brain dead donors (Jay 2011). Eventually, up to 50–65% of the patients with ITBL will require a retransplantation or may die (Merion 2006; Verdonk 2006). Most of DCD organs are discarded because of prolonged warm ischemia time, with most centers declining when longer than 30min. Because of poor results with DCD liver grafts after conventional cold storage preservation, interest in liver machine preservation was renewed (Guarrera 2010). For similar reasoning, interest in lung, heart, and pancreatic machine perfusion has been renewed as well, with aim to expand the donor pool through the resuscitation of extended criteria donor grafts.

Machine perfusion allows the opportunity to repair the damage of warm ischemia and cold storage, reawakens metabolic functions and measures the viability of a graft *ex-vivo* prior to transplantation. However, the simplicity and low cost of cold storage (CS) have kept it the standard of care for transplantation centers. Growing data supports the use of liver machine perfusion preservation, but the variability of systems, techniques, settings, and costs have interfered with standardization and global use. Likewise, heart, lung and pancreatic machine perfusion preservation have a growing body of data demonstrating potential superiority, but the technology has not yet been widely commercialized (Tolboom 2016; Karcz 2010).

The main categorization of machine perfusion preservation has traditionally been by perfusion temperature. Hypothermic machine perfusion (HMP) has been an attractive option to avoid further warm ischemic time and minimize graft metabolic requirements for ease of transport, while still providing oxygenation and metabolic support. Contrarily, much research supports the use of normothermic machine preservation (NMP) to most closely mimic the physiologic environment with oxygenation, nutrition, and full metabolic support. In addition, NMP has the advantage of more thoroughly testing organ functionality (for example bile production and lactate clearance in liver) prior to transplantation, which cannot be tested during hypothermic perfusion preservation. Other researchers have advocated for temperature profiles somewhere in between. Subnormothermic (SNMP) or rewarming machine preservation (RMP) represent some of the newest approaches to both liver and now kidney perfusion in their attempts to maximally increase graft metabolism while minimizing reperfusion injury resulting after cold storage. Optimal temperature, mode of oxygenation, ideal perfusate, perfusion cannulation, and pressure and flow settings are debated, but with little consensus as to ideal perfusion settings, even in kidney where the technology is clinically available. This chapter compiles a summary of the history of machine organ preservation, its most promising research, successful clinical applications, and what the future may hold for kidney, liver, heart, lung and pancreatic machine perfusion preservation.

KIDNEY MACHINE PERFUSION PRESERVATION

History and Introduction

The stilted progression of machine preservation is perhaps best explained by the history of kidney machine preservation. In the 1960s, Belzer et al. started experiments studying

hypothermic machine perfusion (HMP) in canine kidneys and the first successful human transplantation of a hypothermically machine perfused kidney took place in 1968 (Belzer 1967). The perfusion preservation of kidneys first became part of clinical practice in the late 1960s using a perfusate of blood and cryoprecipitated plasma. By the 1970s, HMP was used to preserve and transport kidneys, extending the time grafts could be stored prior to subsequent successful transplantation.

However, after the definition of irreversible coma in 1968, the term brain death became accepted in the early 1970s. Consequently, centers shifted to procure organs from heart beating instead of non-heart-beating (NHB) donors, with increased success rates. The majority of transplant centers abandoned the practice of donation after circulatory death (DCD) due to associated higher complication and failure rates. Additionally, in 1980, the development of UW Solution allowed for 72 hour kidney preservation by simple CS, and use of MP was largely discontinued. Only young trauma patients were considered suitable candidates for DCD donation and these pristine organs were preserved equally well by either static cold storage (SCS) or HMP (Belzer 1980).

Over the last few decades, more marginal donors, as well as DCD donors are accepted to overcome organ shortage which has re-sparked interest in machine perfusion worldwide. Substantial experimental work on machine organ preservation contributed to improved clinical results in extended criteria donor kidney preservation. An international multicenter trial of 672 paired kidneys found that HMP reduced the risk of DGF, and decreased serum creatinine (Moers 2009). Therefore, machine perfusion became the method of choice to obtain good long-term preservation and for the preservation of marginal kidneys.

By 2008, nearly half of U.S. kidney transplants from extended criteria donors (ECD) and 70% of those from DCD donors were machine perfused (Catena 2013). During perfusion, a recirculating perfusate is continuously pumped through the organ vasculature, which can be non-oxygenated or oxygenated. A heat exchanger regulates perfusate temperature at hypothermic (0–4°C), sub-normothermic (20–30°C) or normothermic (37°C) temperatures.

The machine itself generally consists of a circulatory pump (which perfuses the organ *ex vivo*, after procurement) and renal artery cannulation (Jochmans 2016). Continuous perfusion (from procurement to implantation) and pre-implantation perfusion (after a period of SCS and just before transplantation) are the two most commonly used modalities. During perfusion, the kidney is supplied with nutrients and oxygen, has waste products removed, and can be treated with therapeutic agents. Historical challenges which persist today include understanding the metabolic requirement of the *ex vivo* perfused organ, understanding the effect of simple cold storage and the capacity to alleviate reperfusion injury, the development of *ex vivo* viability biomarkers, maintenance of endothelial cell integrity, and the engineering the ideal perfusate delivery system and settings (Belzer 1980).

Hypothermic Kidney Perfusion

Our discussion begins with HMP modalities as these are currently the only widely clinically available machine perfusion technique. HMP places kidney grafts under continuous circulation of a cold perfusate (0–4°C) through the cannulated renal artery immediately after procurement. Circulation of the perfusate is achieved through a device that generates either a continuous or pulsatile flow by a roller pump. HMP maintains hemodynamic stimulation of

the vasculature, known to play a critical role in renal function under normal physiologic conditions. HMP may reduce ischemia-reperfusion (I/R) injury as was suggested by decreased levels of genes that are correlated with I/R injury in HMP kidneys compared to SCS-treated kidneys (Wszola 2014). Zhang et al. observed increased apoptosis in cold stored kidneys versus HMP kidneys in a canine DCD model, with phospho-AKT and ezrin expression induced in the HMP group, implying that cell proliferation, turnover, and renewal are positively influenced by HMP (Zhang 2016). A meta-analysis conducted between 1971 and 2001 showed HMP to be associated with a decreased relative risk of DGF of 0.80 (95% CI = 0.67–0.96) compared to SCS (Jochmans 2015). In 2009, a large randomized controlled trial was conducted comparing continuous HMP with SCS of 336 kidney pairs using the LifePort™, which showed an overall reduced risk of DGF in HMP kidneys compared to SCS kidneys (20.8% vs. 26.5%, $p = 0.05$) with increased one-year graft survival from 90% in SCS kidneys to 94% in HMP kidneys ($p = 0.04$) (Moers 2009).

HMP is thought to be of particular benefit in more marginal ECD grafts, which are particularly prone to IRI, DGF and PNF. A study compared ECD kidneys that were subjected to CS followed by HMP to kidneys that were treated with SCS throughout and HMP-treated organs showed markedly reduced expression of cytokines and soluble intracellular adhesion molecular type 1 (Tozzi 2013). In a study on 91 randomized ECD kidney pairs, HMP compared to SCS significantly reduced the risk of DGF (adjusted odds ratio (OR) = 0.46; 95% CI = 0.21–0.99), reduced PNF (3% vs. 12%, $p = 0.04$) and increased 1-year graft survival (92.3% vs. 80.2%, $p = 0.02$) (Treckmann 2011).

One category of ECD donors is the DCD donor (previously referred to as non-heart-beating) whose cardiac arrest occurs before organ procurement, exposing kidneys to an unavoidable extra period of warm ischemia (WI). Warm ischemia makes DCD organs particularly prone to the development of DGF. The literature reveals conflicting data on HMP in DCD kidneys. Many studies suggest that HMP of DCD kidneys leads to better outcomes, but other studies are not able to show a significant difference in DGF or graft survival. In the multi-center Eurotransplant trial on 82 DCD kidney pairs, HMP showed a reduced risk of DGF compared to SCS kidneys (53.7% vs. 69.5% respectively, $p = 0.025$) (Jochmans 2010). In 2010, Watson et al. published results on a RCT comparing HMP with SCS for 45 DCD kidney pairs which showed no beneficial effect on 1- or 3-year graft survival or DGF for hypothermic machine perfused kidneys (Watson 2010). These contradicting outcomes of the world's currently largest RCTs may be related to timing of HMP throughout procurement and transplantation. Hosgood et al. showed in a porcine kidney transplant model that the beneficial effect of MP disappears when kidneys are not pumped immediately after procurement (Hosgood 2011). In the Eurotransplant trial, kidneys were pumped immediately after retrieval at the donor center, whereas in the U.K. trial, kidneys were cold stored during transfer and HMP was started subsequently. New data suggests that alternative temperature profiles besides hypothermic may be more clearly beneficial in DCD kidneys, particularly those treated with an unavoidable period of SCS (Bagul 2008; Hosgood 2013; Hosgood 2011).

HMP Preservation Solutions

Countless preservation solutions have been created and trialed, all with different compositions aimed to prevent IRI and maximize graft survival and function. Early preservation solutions consisted of diluted blood and ringers lactate solution. Currently, the most commonly used preservation solutions are University of Wisconsin (UW), histidine-tryptophan-ketoglutarate (HTK), Celsior, Institute George-Lopez (IGL-1), Polysol, EuroCollins, hypertonic citrate or Marshall solution (HOC), and phosphate-buffered sucrose (PBS).

In 1987, Belzer and colleagues developed the University of Wisconsin (UW) solution (also known as KPS-1 or Belzer's solution) and this became the gold standard among organ preservation solutions. In the European Multicenter Trial, the use of UW versus EuroCollins solution significantly reduced the rate of DGF (10% vs. 23%) (Ploeg 1992). UW shows good outcome of short- and long-term kidney preservation, but the main disadvantage is its high viscosity mainly due to hydroxyl ethyl starch (HES) (Catena 2013). For HMP, UW-G is used, in which a more extracellular solution is achieved through replacing lactobionate by gluconate and reducing the potassium level (Catena 2013).

Some institutions favor low-viscosity HTK solution to preserve DCD kidneys. HTK was introduced in 1980 by Bretschneider and is recommended in HMP at low pressures and in high perfusion volumes. More recently, Rauen and De Groot developed Custodiol-N solution as improved modification of the former HTK solution with iron chelators to inhibit cold-induced free radical-mediated injury, shown to be efficacious in protecting rat livers during HMP (Stegemann 2010). Developed in 1994, Celsior solution is a colloid and combines the osmotic efficacy of UW (lactobionate and mannitol) with the potent buffering ability of HTK (histidine), with the benefit of reduced tissue edema from hydrostatic pressure since Celsior contains macromolecules that do not pass the cellular membrane (Catena 2013).

The fairly new preservation solution IGL-1 combines the advantages of UW and Celsior with high sodium concentration and polyethylene glycol (PEG, 35 kDa), substituting HES. A non-randomized prospective multi-center study showed the same effectiveness for IGL-1 versus UW solution, but lower costs favor the former (Codas 2009). Polysol, a new low-viscosity preservation solution, is introduced to facilitate transplantation of ischemically damaged organs. Amino acids, vitamins, potent buffers, and anti-oxidants have been added to support metabolism during HMP (Bessemers 2005). One of the main components is PEG 35, a low-molecular-weight colloid that does not increase viscosity as seen with HES-containing solutions. Polysol is currently used in experimental settings only, but recent reports seem promising. A study in a porcine auto-transplant model reports better preservation of microcirculation and renal function after 20-h SCS preservation compared to UW (Schreinemachers 2009).

HOC, or Marshall's solution is extensively used for clinical transplantation in the U.K. and Australia. HOC is an intracellular solution with high potassium content, mannitol as the impermanent ion, and citrate as its buffer. The hypertonic character of HOC prevents entry of fluid into the cells and has shown to be effective for 72-h canine kidney preservation (Kay 2009).

Oxygenation during HMP

In HMP, oxygenation plays a central role of importance for reconditioning organs after ischemic time. Lack of oxygen leads to ATP decrease, which can be as large as 80% for kidneys (Jassem 2004). Continuous oxygenation during perfusion is thought to be useful to support the metabolic demand of the organ. However, high concentrations of oxygen are believed to favor the production of oxygen free radicals and promote adverse effects on tissue during long-term oxygenated preservation (Stegemann 2010; Rauen 2004). Many studies strongly suggest oxygen to be a constitutive adjunct in HMP, improving functional outcome of the graft. Hoyer and colleagues showed that HMP with 100% oxygen results in higher flow and lower renal resistance (RR) during perfusion and improved graft function as compared to oxygen-free HMP (Hoyer 2014). Positive results for oxygenated HMP were confirmed with a 3 month post-transplant follow-up by showing lower serum and peak creatinine levels and injury markers, which correlated with improved longer term outcomes of lower serum creatinine, less proteinuria and less chronic kidney fibrosis (Thuillier 2013). Kron et al. investigated the effects of 1 hour hypothermic oxygenated perfusion (HOPE) following a period of CS and immediately prior to transplantation, with dramatic improvements in graft function after transplantation as shown by decreased nuclear injury, macrophage activation, endothelium activation, tubular damage, and improved graft function (Kron 2016). Grafts exposed to warm ischemia, simulating DCD, seem to particularly benefit from oxygenated perfusion with restored ATP stores in DCD porcine kidneys, but no added benefit of oxygenation was found in kidneys without injury (Buchs 2011).

Commercial Hypothermic Machine Perfusion Devices

As HMP is gaining recognition, more perfusion machines are becoming available. (For more details see the chapter Isolated Kidney Perfusion Models). The most commonly used device in Europe and the USA is the pressure-driven LifePort Kidney Transporter (Organ Recovery Systems, Itasca, IL, USA). Another commercially available system is the flow-driven Waters Medical RM3 (Birmingham, AL, USA). In both systems, the operator can modify the systolic perfusion pressure, with flow and resistance recorded over time. Relevant differences between the systems are related to the way both devices generate and control flow and pressure. The RM3 uses a flow-driven system, which requires 50% higher systolic pressures (45 vs. 30 mm Hg) to obtain similar flow rates. A comparative study on both systems demonstrated minimal differences in early kidney recovery, but significantly higher levels of post-transplant fibrosis in kidneys preserved by RM3 compared to LifePort (Wszola 2013). Another study showed favorable results for the LifePort device compared to RM3 with shorter duration of DGF after transplant, lower incidences of interstitial fibrosis and tubular atrophy in biopsies taken within 1-year post transplant, and lower renal resistance during perfusion (Wszola 2013).

Sub-Normothermic Kidney Perfusion

The interest in sub-normothermic machine perfusion (SNMP) increased as an attempt to alleviate or prevent organ injury caused by a sometimes unavoidable period of SCS preservation, which seems to be especially damaging to DCD organs. In a porcine model of renal I/R injury, oxygenated SNMP demonstrated better protection of the organ compared to cold storage. Moreover, SNMP grafts showed nearly twofold better values of creatinine clearances compared to oxygenated HMP. SNMP also permits higher pressure perfusion with reduced risk of endothelial and vascular impairment, as higher temperatures increase vascular compliance (Hoyer 2014). Higher temperatures also lead to higher metabolic demands requiring active oxygenation and sufficient perfusion flow. The use of SNMP in clinical kidney transplantation has not yet been reported.

Gradual Rewarming

Another experimental machine perfusion temperature profile is gradual rewarming based on the hypothesis that ischemic damage results from the abrupt temperature shift from hypothermia to normothermia, leading to mitochondrial dysfunction and proapoptotic signal transduction (Hoyer 2016). Recent studies have investigated the effect of the controlled oxygenated rewarming (COR), a concept that originated in liver perfusion due to logistical necessities of a period of SCS prior to machine perfusion. Schopp et al. reported a nearly twofold increase in renal clearances of creatinine and urea after COR of pig kidneys compared to controls. This was accompanied by significantly improved renal oxygen consumption and less cellular apoptosis (Schopp 2015). Similarly, Mahboub et al. demonstrated lower levels of transaminases, and heat shock protein 70, ICAM-1, VCAM-1 mRNA expressions were decreased in gradually rewarmed kidneys. Kidneys that underwent gradual rewarming suffered less renal parenchymal tubular injury and showed better endothelial preservation (Mahboub 2015). These data suggest that a gradual increase in temperature results in better energetic recovery, less cellular injury, and ultimately superior function of kidneys subjected to COR, however, there have been no clinical applications in kidney perfusion to date.

Normothermic Kidney Perfusion

In contrast to cold preservation, the concept of normothermic machine perfusion (NMP) is to closely replicate the physiological environment and maintain cellular metabolism during preservation. With aerobic metabolism restored, the kidney grafts regain function and minimize cold ischemic insult, thought to be preferred in the resuscitation of DCD and ECD kidneys. NMP has been shown to replenish ATP stores and up-regulate repair mechanisms such as heat shock protein 70, which aids repair due to oxidative damage (Hosgood 2013). However, the act of rewarming may aggravate inflammatory processes and increase graft injury, particularly without optimal perfusion settings, nutrients and oxygenation profiles. Proinflammatory cytokines, such as IL-6, are upregulated in response to ischemic injury and were released in the kidney during reperfusion after NMP (Hosgood 2013). Alternatively, IL-

6 can also have anti-inflammatory properties in resolving tissue damage after an initial inflammatory response (Nechemia-Arbely 2008).

Ex-vivo NMP should most ideally be used throughout the preservation interval, which is logistically difficult due to tenuous perfusion requirements. Alternatively, NMP can be implemented for a shorter period prior to transplantation as a form of graft resuscitation. One practical proposed approach is to use 1–2 hours of NMP as a restorative period prior to transplantation to allow graft function and replenish ATP stores (Bagul 2008; Hosgood 2013; Hosgood 2011). NMP-resuscitated kidneys had less tubular injury, improved blood flow and oxygenation and were metabolically more stable as compared to the cold stored kidneys. In 2011, Hosgood et al. reported the first case of successful kidney transplantation in man after the organ was cold stored for 11h, followed by 35 min of *ex vivo* NMP. The 55-year old recipient had slow graft function, but ultimately remained dialysis independent (Hosgood 2011). A pilot clinical study compared 18 ECD kidneys that received 1h of pre-implantation blood-based NMP with 47 matched SCS controls. Significantly lower DGF rates were observed with pre-implantation NMP (5.6% vs. 36.2%, $p = 0.014$) (Hosgood 2013).

Since DCD and ECD organs poorly tolerate the effects of hypothermia in SCS, a more novel approach of NMP totally avoids storage in hypothermic conditions. A study by Kathis et al. demonstrated that NMP with an erythrocyte-based solution could replace hypothermic storage techniques. NMP kidneys showed similar serum creatinine levels and creatinine clearance post-transplant compared to SCS grafts. After 10 days follow-up, NMP animals had serum creatinine and blood urea nitrogen values comparable to basal levels, whereas SCS grafts showed elevated values (Kathis 2016). Recently, Hosgood et al. reported the successful transplantation of a pair of human kidneys that were deemed unsuitable for transplantation due to inadequate perfusion, but subsequently were transplanted after perfusion and assessment using *ex vivo* NMP (Hosgood 2016).

Normothermic Preservation Solutions

Continuous perfusion with an oxygenated solution to support aerobic metabolism is key under normothermic conditions. During NMP, the perfusate can be based on either a natural oxygen carrier such as blood or an artificial-based medium. Early preservation solutions consisted of diluted blood and Ringers lactate solution. From 1985 until 1993 Collins or Euro-Collins solution was the commonly used solution, and from 1993 onwards, this shifted to UW, which is still the gold standard for abdominal organ preservation today (Wight 2003).

Brasile et al. were the first to develop an acellular normothermic solution based on perfluorocarbon (PFC) emulsion and enriched tissue culture-like medium containing essential and non-essential amino acids, lipids and carbohydrates (Brasile 1994). PFCs are inert solutions that have a high capacity for dissolving oxygen. New, more stable, PFCs are now being developed mainly as blood substitutes. Humphreys et al. recently used a commercially made PFC to provide oxygenation and reduce ischemic injury to the kidney during warm ischemia by retrograde infusion through the urinary system (Humphreys 2006). These new generation PFCs could potentially be developed as normothermic preservation solutions. However, due to complexity of manufacturing, they are very expensive. A more stable pyridoxalated haemoglobin polyoxyethylene (PHP) solution has proven to be more successful and Brasile et al. have since replaced the PFC with this solution (Stubenitsky 2000). Other

solutions such as Lifer (an artificial preservation medium containing a non-protein oxygen carrier, nutrients and growth factors) have also been used during NMP. Some studies have shown higher flow rates in Lifer perfused kidneys compared to UW (Gage 2009; Olschewski 2010). The most newly reported acellular solution is Hemarina-M101, extracellular hemoglobin derived from a marine invertebrate. It has been formulated into an oxygen carrier mainly as a blood substitute. M101 has been used in SCS to deliver oxygen with favorable results and functions over a wide range of temperatures (4–37°C) (Thuillier 2011).

A blood-based solution during NMP was previously considered limited due to hemolysis, platelet activation, deterioration of red blood cell oxygen-carrying capacity, high intra-renal resistance and tissue edema (Thiara 2007). However, results of an isolated perfusion system with 1 unit of compatible packed red blood cells mixed with a priming solution and added protective agents are promising. In a series of 18 ECD kidneys, DGF was 5.6% compared to 36% in similarly matched recipients of a kidney undergoing SCS (Nicholson 2013).

Normothermic Machine Perfusion Viability Assessment

In contrast to HMP, kidney function can be evaluated during NMP by directly assessing functional measures such as blood perfusion, renal blood flow and urine output. Recently, Hosgood et al. used *ex vivo* NMP to develop a novel scoring system for pre-transplant assessment of marginal kidneys (Hosgood 2015). Based on assessment scores from their clinical series, it became clear that kidneys with a score of 1 to 4 could be transplanted successfully. Kidneys with a score of 5 would be considered very high-risk and unlikely to be suitable for transplantation. In their study on 36 kidneys, grafts with an assessment score of 3 had a significantly higher incidence of DGF (38%) compared to kidneys with a score of 1 (6%) or 2 (0%) ($p = 0.024$). The ability to assess organs adequately prior to transplantation is an especially important benefit of *ex-vivo* machine perfusion and is an especially powerful use for NMP.

LIVER MACHINE PRESERVATION

History and Introduction

In 1935, Alexis Carrel and Charles Lindbergh designed the first liver perfusion machine using pressure-controlled, oxygenated normothermic perfusate in a glass device (Dutkowski 2008). In spite of significant technical advances, no system has been proven to clinically significantly extend the length of *ex vivo* organ viability as compared to CS in preservation solutions such as University of Wisconsin (UW), Histidine-Tryptophane-Ketoglutarate (HTK) and Celsior. After the first unsuccessful attempts of hypothermic perfusion of human livers by Starzl et al. in 1967, the clinical use and development of human liver perfusion devices did not move forward (Starzl 1967). Because of the success of cold storage preservation in UW solution, there was no need to use machine preservation until the use of marginal livers became necessary due to increased discrepancy between demand and supply. Several clinical trials now support the preferred use of machine perfusion in grafts which

have been subjected to warm ischemic time, but the ideal machine perfusion set-up and settings are still very much debated. In 2010, Guarrera et al. reported the first successful human liver transplantations following hypothermic machine perfusion preservation (Guarrera 2010). More recently, Dutkowski has examined matched case analyses of HMP vs. cold storage with marked decrease of intrahepatic cholangiopathy, biliary complications and improved 1 year graft survival (Dutkowski 2015). In 2016, Bral et al. published the first clinical normothermic machine perfusion transplantation series, demonstrating feasibility and safety, but bringing to light the questions of ideal methodology (Bral 2016).

Liver Perfusion Route

Given the unique physiology of liver perfusion *in vivo*, several perfusion routes have been advocated for machine liver perfusion. Portal vein only perfusion is commonly used in rat liver perfusion for simplicity reasons, but is generally believed inferior for larger animal models and humans. Arguments for hepatic artery perfusion include perhaps superior oxygen supply to the peribiliary vascular plexus (Bruggenwirth 2016). Although it has been reported that the biliary ducts also have blood supply from the portal vein (Sliker 2012), the biliary tract is mainly supplied with arterial blood through the Peribiliary vascular plexus (PVP) and therefore, any injury to the PVP may contribute to the ischemic death of the biliary epithelial cells after transplantation (Nishida 2006). The importance of hepatic artery perfusion is illustrated by the high incidence of biliary necrosis and strictures after hepatic artery thrombosis (HAT) in patients after liver transplantation (Mourad 2014). Additionally, during early reperfusion, the O₂ delivery is heavily dependent on arterial flow and as a result, dual perfusion is superior to portal perfusion in bile production as well as output of phospholipid, cholesterol and bilirubin (Foley 1999, 2003). Combined arterial and portal machine perfusion of DCD porcine livers also results in a better preservation of the PVP and less arteriolonecrosis (Op den Dries 2014).

Hepatic artery perfusion alone seems to be less beneficial than portal vein or dual perfusion (Compagnon 2001). All trials of NMP, SNMP or rewarming machine perfusion (RMP) utilized dual perfusion circuits, as these methods attempt to approximate physiologic conditions and maximize oxygenation. Most HMP studies also utilized dual perfusion circuits with few studies demonstrating portal vein perfusion only. Portal vein only studies state goals such as simplifying machine perfusion or improving machine portability. No study argues portal vein only perfusion to be superior or even comparable to the benefits of a dual perfusion system (with the exception of Schlegel et al. in the setting of HMP (Schlegel 2015)). Dual porcine machine perfusion through hepatic artery (HA) and portal vein (PV) appears to be more effective at alleviating reperfusion injury than either portal vein or hepatic artery alone (Foley 1999).

The physiology of liver perfusion is notably complex, and is an additional reason for dual perfusion that it most closely mimics *in vivo* mechanics. For example, one study showed the principle of *ex vivo* flow competition: arterial pressure alters portal flow (Monbaliu 2012). For reasons of functional rejuvenation of liver tissue as well as providing consistent physiology-mimicking perfusion, most researchers choose dual perfusion in porcine machine liver perfusion models, and this practice has transferred over to the first trials in human livers.

Normothermic Liver Perfusion

The tenant of NMP has long been the replication of physiologic parameters to minimize ischemia and maximize *ex vivo* metabolism. Hence, most NMP trials utilize modified heparinized blood solutions or Steen solution plus erythrocytes as the perfusate (Monbaliu 2012; St Peter 2002; Reddy 2005; Xu 2012; Knaak 2014; Liu 2014; Schon 2001). Other studies have utilized Celsior (Gringeri 2012), Steen (Boehnert 2013), Custodiol (Minor 2013), or UW gluconate (Obara 2013) or Modified nutritive Williams' medium E (Izamis 2014) as perfusate. Liu et al directly compared Steen Solution vs. Steen with erythrocytes vs. whole blood with the result that aspartate aminotransferase (AST), alanine aminotransferase (ALT) and LDH production was decreased and bile production was increased with improved histology in the groups with erythrocytes or whole blood, emphasizing the importance of an oxygen carrier in NMP. All NMP studies utilized dual perfusion routes, mimicking physiology and perfused for a minimum of 3 hours up to as long as 24 hours (Liu 2014). Early studies were aimed to lengthen liver storage up to 72 hours (Butler 2002). Other proponents of NMP claimed that it decreased ischemia reperfusion injury and resulted in superior bile production (Imber 2002; St Peter 2002). All NMP studies utilize oxygenators. Perfusion was controlled by either pressure or flow with flow being less popular at 5 out of 16 studies and a few studies using flow for hepatic artery (HA) and pressure for portal vein (PV) or vice versa. Goal pressures ranged from 50–100 mm Hg for the hepatic artery and 3–10 mm Hg for the PV. Flows ranged from 150–700 mL/min for HA and 950–1750 mL/min for the PV, with a few studies reporting flow as a function of liver weight at HA 0.16–0.25 mL/min/g and PV as 0.22–0.8 mL/min/g.

The benefits of NMP are nearly undisputed in the literature, but the addition of NMP into clinical practice is logistically complicated. Now that CS is the established standard preservation, and most centers lack perfusion machines, some period of CS in clinical practice is unavoidable. Four hours of CS prior to NMP results in statistically significant reduction in bile and Factor V production, reduction of glucose stores, increased release of AST and ALT, and base excess and endothelial injury, as shown through increased hyaluronic acid as well as necrosis in histology, and none of these parameters were normalized if NMP was performed following CS (St Peter 2002).

Subnormothermic and Rewarming Liver Perfusion

The unavoidable period of CS has brought upon newer variations of NMP where the liver is perfused either at subnormothermic temperatures or the perfusate is gradually rewarmed from cold storage to normothermic temperatures. Initial perfusion at a cold temperature enables replenishment of cellular energy stores in order to reduce ischemia reperfusion injury upon rewarming. Subnormothermic Machine perfusion (SNMP) was shown to improve tissue energetics, peroxidation and increased bile production (Minor 2013) as well as better recover homeostasis, oxygen consumption, bile production and histology (Knaak 2014). However, others have found decreased bile production, increased AST/ALT and worse histology using SNMP (21°C) versus NMP (38.5°C) (Nassar 2016). Temperature controlled rewarming has been found to result in decreased release of LDH and superior mechanistic properties of the livers such as pressure curves (Obara 2013). Gradually warming warm-ischemic treated livers to

normothermic perfusion or subnormothermic perfusion was also shown to lower liver enzyme release, increase ATP stores, improve bile production and improve histology as compared to hypothermic or subnormothermic perfusions (Minor 2013; Furukori 2016). Most recently, rewarming perfusion was shown to improve international normalized ratio (INR) (marker of coagulation factor production), bile production as well as minimize sinusoidal endothelial cell injury and activation of Kupffer cells. However, extending the rewarming phase to 60 or 120 min rather than 20-30min decreased synthetic liver functions perhaps by increasing anaerobic respiration time (Banan 2016). Preliminary studies also suggest a period of in situ subnormothermic extracorporeal membrane oxygenation (ECMO) prior to rewarming compounds the benefits of subnormothermic machine perfusion (SNMP) on resuscitation of livers after (warm ischemic time) WIT (Hagiwara 2016). Others found that gradual increase of perfusate flow and oxygen throughout the rewarming period minimized AST/ALT release (Morito 2016). Controlled oxygenated rewarming perfusion (COR) was also shown to be superior in recovering energy stores and minimizing hepatocellular and mitochondrial damage after 18 hours of CS as compared to NMP (Hoyer 2016). COR also resulted in lower mitochondrial caspase-9-activity. Significantly lower enzyme leakage and higher bile production were also observed during reperfusion. The first clinical application of COR has recently been successfully applied in liver transplantation (Hoyer 2016).

Hypothermic Liver Perfusion

In contrast to NMP settings, HMP settings are by definition, not particularly physiologic, with perfusate temperature most commonly defined as 4 C. Many porcine HMP studies used KPS-1 Solution (Jain 2004, Monbaliu 2007, Vekemans 2007), while many others used UW Solution or Belzer MP (Obara 2012; Schlegel 2013). Bessems et al. was unique in comparing Celsior perfusate versus Polysol with the result that Celsior solution was more damaging than Polysol, increasing AST/ALT and intravascular resistance to a greater extent (Bessems 2006). (For more detailed discussion of perfusion solutions see above where we discussed kidney perfusion). Most studies, besides the exceptions noted in section “perfusion routes,” used a dual circuit (portal vein and hepatic artery perfusion) and most recent studies seem to agree that dual circuit HMP seems more beneficial. In many studies, the lengths of perfusion for HMP were much longer than NMP, up to 24 hours, as HMP is looked at as a potential means to extend the storage time of donated livers. Most studies since 2013 have focused on recovery of donor livers from warm ischemia time and have shorter perfusion times ranging from 1 to 4 hours. Most studies used pressure-controlled circuits with hepatic pressures 20–30 mm Hg (exception Monbaliu with increasing pressures to 55 then 70) and portal pressures 3–13mm Hg with the majority limited to less than 7 mm Hg.

Studies in 2005 through 2007 focused on defining the capabilities of HMP. HMP was shown to maintain superior oxygen consumption and decrease ALT when compared to cold storage (Jain 2004). A portable perfusion machine was shown to maintain a liver for 24 hours with no significant histological damage (van der Plaats 2006). The pattern of decreasing HA vascular resistance over the first 6 hours of perfusion was first noted by Monbaliu et al. Also noted in this study was the introduction of anoxic vacuoles by HMP, likely due to lack of oxygenation in this study, and inability of their HMP livers to produce bile *ex vivo*. Another study showed increased ATP stores after HMP, indicating better preservation of energy stores

as well as use of an oxygenator directly protecting against anoxic vacuolization (Vekemans 2007).

Predicting Pretransplantation Viability

A strong argument for the use of machine preservation is the added ability to assess viability of donor liver grafts prior to transplantation. Proposed outcome measures include flow and pressure characteristics and perfusate enzymes such as AST and LDH. The assessment of liver grafts is complicated by its unique dual blood supply, and the wide ranged and low flow portal system. Obara et al. found that hepatic arterial pressure, AST and LDH correlated well with warm ischemia time (WIT) during HMP (Obara 2012). Logically, oxygen consumption, complement/factor V production, bile production, and hyaluronic acid (marker of endothelial injury) have been used as outcomes and their levels correlated to damage found in histology. Other recent studies suggest the use of microRNA profiles of perfusate samples as indicators of WI injury and prediction of PNF. One miRNA, miR-22, was correlated to transplantation survival outcome, but is believed to have low diagnostic potential (Khorsandi 2015). Further work must be done to establish the best *ex-vivo* markers of WI injury and reperfusion injury to determine the best predictors of good transplantation outcomes.

When focusing on histologic changes caused by warm ischemia, it is important to perform reperfusion with whole blood because it magnifies ischemia reperfusion injury (IRI). Whole blood has all the key players of ischemia reperfusion injury, namely the complement system, white blood cells, and platelets. One cannot expect to see all the changes associated with IRI if the liver is not perfused with blood experimentally. Likewise, clinically it is difficult to assess the degree of IRI during HMP as the liver becomes metabolically less active and NMP allows for improved functional assessment *ex vivo* prior to transplantation. Despite many failed attempts to quantify in an experimental setting the impact of HMP using whole blood reperfusion, Op Den Dries et al. showed after 30 minutes WI and no CS, that HA flow and ATP content increased after HMP, while AST and LDH decreased significantly. HMP-treated livers also showed improved histology and lower caspase-3 levels. This study was also significant for the use of miRNA and the establishment of miRNA profiles in the porcine model which may be helpful in profiling livers damaged by WI (Op den Dries 2013). After 60 minutes WI and 5 hours CS, Schlegel et al. found that the effects of 1 hour of hypothermic oxygenated portal perfusion on NAD^+ , CO_2 , Cytochrome C, AST, HMGB1, histology, $\text{TNF}\alpha$ resulted in decreased cytochrome C, HMGB1, AST and better histology with reduced Kupffer cell activation (decreased $\text{TNF}\alpha$). This study also compared low perfusion pressures to high perfusion pressures, showing that low pressure perfusion (3 mm Hg) was superior to high (8 mm Hg) (Schlegel 2013). Liu et al. studied pH, AST, L-fatty acid binding protein (L-FABP), ATP and redox-activated iron after 0–120 minutes WI and no CS, attempting to create a damage index predictive of ischemia reperfusion injury. AST level and pH in the perfusate proved the most valuable predictors studied (Liu 2014).

Shifting attention to potential *ex-vivo* assessment, a recent review by Verhoeven et al. showed that bile production during NMP correlated well with early graft survival, as did bilirubin and phospholipid concentration, which are increased by NMP (Verhoeven 2014). Impaired secretion of phospholipids after CS may result in a high bile salt/phospholipid ratio

known to be toxic to cholangiocytes and associated with the development of ITBL. Hepatocyte injury is generally measured by release of AST, ALT, and LDH into the perfusate, and is correlated with both warm ischemia time and poorer survival post transplantation. Traditionally, energy status is recorded by ATP levels, hyaluronic acid and thrombomodulin have become established markers for endothelial injury. Inflammatory markers such as TNF- α levels are shown to correlate positively on histology with Kupffer cell activation. Peribiliary epithelial and vascular injury is represented by arteriolosclerosis and changes in the luminal size of the portal vein branch, but these changes were only present after reperfusion. Lastly, a particular profile of miRNA in the bile is associated with later development of ischemic type biliary injury (Khorsandi 2015).

Future of Clinical Liver Machine Perfusion

Nearly a century of experimental *ex-vivo* machine perfusion of livers has left modern medical science in much the same place it started: What is the clinical role for *ex vivo* liver perfusion and how can it best be implemented? Recent breakthroughs finally may show what clinical liver machine perfusion may look like. Simple cold storage in UW Solution has become the gold standard worldwide such that any proposed perfusion must accept some period of interim cold storage prior to perfusion and that the perfusion must add some benefit beyond simple cold storage. At one point, the goal was to increase the length of the organ's viability as compared to cold storage, but with modern transportation and the organ donation system, machine perfusion has not been rigorously shown to be effective in this regard. Modern goals of machine perfusion look towards restoring organ damage, for example extending donor criteria by alleviating damaging effects of warm ischemia in DCD livers. Additionally, modern perfusion systems look to test viability and predict dysfunction of donated livers prior to transplantation. Reviewing the successes and pitfalls of various machine perfusion techniques can show us where the greatest successes have been and where future studies should focus their energies.

As early as 1970, Belzer et al. showed the promise of NMP in maintaining livers *ex-vivo* by showing equivalent outcomes after 8–10 hours NMP as compared to immediate transplantation. Schon et al. showed that 4 hours of NMP could reverse histology, bile production, alpha GST and AST levels after WI injury, and prevent the PNF seen within 24 hours of non-perfused livers (Schon 2001). However, many of these studies included no CS time. Brockmann et al. also showed improved survival with 5 or 20 hours of NMP, particularly in organs that had been severely ischemic (after 40 minutes of WI injury) (Brockmann 2009).

Of the porcine liver hypothermic machine preservation (HMP) studies, results have shown promising resuscitation of WI damaged livers, but the aspect of reperfusion injury remains largely untested. Obara et al. showed promise with the HA normalized pressure recovery to baseline with 2–3 hours of HMP. Li et al. were only able to show slightly delayed morphologic change, apoptosis and release of AST/ALT with cold storage as compared to CS (Li 2015). De Rougemont et al. showed HMP increased glutathione stores and arterial pressure and HMP liver recipients survived whereas CS recipients did not (de Rougemont 2009).

In trials of transplantation after HMP, no benefit is seen as compared to cold storage (Guarrera 2004) except in the resuscitation of unsalvageable livers after 60 min warm ischemia (de Rougemont 2009) where transplants were viable only after HMP, and had improved GSH stores and arterial pressure. Many pig liver transplant studies showed survival rates after WI and HMP as low as 33% (Vekemans 2009) and 20% (Fondevila 2011), speaking both to the technical difficulty of the porcine transplantation model and the livers sensitivity to warm ischemia. Most promising were livers with only 30 min warm ischemia for which HMP improved survival from 0% in CS to 75% in HMP with lower AST and LDH (Shigeta 2012). While histologically and biochemically HMP-treated porcine livers were better preserved as compared to CS, the liver viability is still less than excellent in these preclinical trials.

The clearest side by side demonstration of the effects of NMP, HMP, and rewarming machine perfusion (RMP) comes from a study by Shigeta et al. who studied porcine livers after 60 min WI and 2 hours CS and compared $n = 3$ orthotopic liver transplantations after 2 hours of either NMP, HMP, or RMP. In 24 hours, the study found that all NMP and HMP livers suffered PNF with 0% survival, with 75% survival and improved histology in the RMP group (Shigeta 2013). Others have been able to show 100% survival after no warm ischemia and preservation at 21°C RMP with total alleviation of post reperfusion syndrome, lower AST/ALT and less centrilobular necrosis. RMP transplants were perfused in UW gluconate solution with added branched chain amino acids, with the SNP livers perfused using cell-free bovine-derived hemoglobin with hetastarch colloid (Fontes 2015).

The porcine model has provided a stepping stone and a wealth of iterative learning about *ex-vivo* liver machine perfusion preservation. With physiological, anatomical and immunological properties similar to humans, porcine livers have allowed the modeling of warm ischemia and ischemia reperfusion injury as well as establishing markers predictive of post-transplantation outcomes. With SNP and RMP, studies are showing clinically applicable methodology which is improving post-transplantation outcomes with modeled extended criteria donors. The potentials of SNP and RMP perfusions are clear to see, as more and more researchers are publishing results preferring these temperature settings. It has not been fully defined how slowly livers should be rewarmed, the critical temperature the liver must reach, and the length of warm perfusion needed to maximize metabolic parameters. Finally, researchers are producing clinically viable solutions to extending liver donation criteria to include DCD livers. Future studies should focus on essential requirements for limits of recoverable warm ischemic time, limits for length of CS prior to perfusion, in addition to perfusion settings, and upon ideal perfusion time to maximize liver viability. Additionally, studies which follow porcine perfusion transplantation models for three to six month would expand our understanding of the development of ischemic cholangiopathy and consequent biliary stenosis, and potentially protective role of machine perfusions. Before clinical implementation of machine perfusion preservation, *ex-vivo* markers which reliably predict major transplantation outcomes, such as primary non-function and early allograft dysfunction, must be established.

Lastly, we turn our attention towards machine preservation which has been implemented in human trials. Implementation of HMP after a period of CS for ECD human livers was shown to improve ATP stores and result in increased bile, bilirubin and bicarbonate production, but was not able to reduce hepatobiliary injury as measured by AST, ALT, LDH and gamma-glutamyl transferase as tested with NMP simulated transplantation (Westerkamp

2016). However, in a matched graft study of two European hospitals, DCD livers treated with oxygenated HMP prior to transplantation had reduced ALT, cholangiopathy, biliary complications and improved 1-year graft survival compared to SCS-treated DCD grafts, and decreased necessity of retransplantation (18% SCS to 0% HMP) (Dutowski 2015). The first ECD human liver was transplanted after resuscitation with NMP in 2015 (Perera 2016) with subsequent studies summarizing their results (Mergental 2016). Recently, a single-center study in Canada showed the feasibility of ten human DCD livers treated with NMP for a mean of 11.5 hours prior to transplantation, with a small decrease in six-month graft survival in NMP-treated livers (80%) versus SCS livers (100%), demonstrating the technical difficulty of implementing liver NMP clinically (Bral 2016). Additionally, the superiority of COR and SNMP in porcine livers sparked the first successful application of COR in liver transplantation (Hoyer 2016). Rewarming therapies, the newest methodology in machine preservation, may become the ultimate compromise with their ability to capture advantages of relative convenience as compared to NMP, longevity of storage comparable to HMP or SCS, optimal resuscitation in predictive animal models, and *ex-vivo* assessment prior to transplantation. After nearly 60 years of experimental liver machine perfusion, we may soon see its role develop in clinical medicine. Now that trials are honing in on the particulars of a protocol for superior liver machine preservation, trials need to be thorough about reporting their perfusion results to allow for comparison and pooled analysis among clinical trials (Karangwa 2016).

Heart Machine Preservation

As with the liver, technical difficulty in cannulation and determination of perfusion settings has limited clinical applicability of machine perfusion. However, the heart is unique in that current preservation techniques and transplantation guidelines severely limit the number of usable grafts which can be matched with a recipient. Nearly 50% of discarded heart donations could have been used if a suitable recipient was available within the time constraints of modern heart transplantation (DiMaio 2013). Additionally, DCD heart donations are critically limited due to the unavoidable period of warm ischemia. HMP has produced encouraging results in porcine hearts subjected to warm ischemia, increasing energy stores, decreasing lactate levels and increasing contractility as compared to CS in simulated transplantation (Van Caenegem 2016). HMP has the capability to better preserve ultrastructure compared to CS as seen by electron microscopy with decreased muscle fiber and endothelial cell damage and less apoptosis (assessed by TUNEL) as compared to cold storage (Michel 2015). Most perfusion attempts have focused on perfusion via the aorta, which is limited by aortic valve incompetence. One recent study showed promising results of canine hearts treated with hypothermic retrograde perfusion via the coronary sinus, allowing for 14 hour preservation, increased pre-load recruitable stroke work and decreased creatinine kinase release as compared to SCS hearts, but unfortunately showing no differences in histological assessment of cell death (TUNEL) (Brant 2016.) Retrograde perfusion raises concerns over inferior right ventricle (RV) perfusion, and canine hearts did show decreased RV perfusion, with no RV dysfunction noted upon transplantation. The same retrograde system as applied to human hearts showed preservation of oxidative metabolism and low lactate-to-alanine ratios, suggesting superior RV tissue protection (Cobert 2014). Another

concern with regards to machine perfusion of the heart in general is the resultant interstitial edema which results in graft weight increase prior to transplantation, but this edema has not been clearly proven to diminish graft function (Brant 2016).

Normothermic perfusion has also been trialed in heart resuscitation prior to transplantation, as a reconditioning method following cold storage and prior to transplantation. As found in the liver, NMP more closely mimics human physiology resulting in superior *ex-vivo* assessment of organ functionality. Phase I Trials of the prospective multicenter European Trial to evaluate the safety and performance of the Organ Care System for heart transplants (PROTECT) and effectiveness evaluation (PROCEED) both showed promising results for heart NMP with whole blood perfusate, with 100% and 93% survival at 30 days, comparable to CS (McCurry 2008). It has since been found that functional parameters such as stroke work, ejection fraction and ventricular relaxation measured during NMP better predict myocardial performance as compared to metabolic parameters (White 2015). One study found rat hearts subjected to WI and CS time had improved contractility after normothermic reconditioning (Tolboom 2015). The same group recently compared normothermic resuscitation to subnormothermic (SNMP) at 20°C with superior preservation in the SNMP group with decreased troponin-t levels and higher ATP stores (Tolboom 2016). As has been found in liver perfusion, there may be a role for SNMP or rewarming perfusion as a compromise between the longevity benefits of hypothermic perfusion and the resuscitation and assessment capabilities of normothermic perfusion. As researchers learn more about heart machine preservation, many hope that clinical implementation of machine perfusion will increase the quality of DCD and ECD grafts and enable distant procurement for dramatic increase of the heart donor pool.

Lung Machine Preservation

As with DCD hearts, DCD lungs are fragile and often critically damaged by warm ischemia. Indeed, 80% of potential brain death donor lungs are injured in the intensive care unit and deemed unusable for transplantation (Cypel 2009.) Therefore, machine perfusion capable of reconditioning and repairing damaged grafts possesses the potential to drastically increase the donor pool. Lung machine preservation is unique among organ machine perfusion in that evaluation of high-risk graft function is a necessity rather than an improvement, and machine perfusion could additionally be used to treat and repair lung grafts. Preclinical trials have thus far focused on hyperoncotic perfusates to intentionally draw fluid from the intravascular space to decrease lung edema. A few early trials showed promising results with HMP. HMP was used as a delivery system for oxygen free radical scavengers in canine heart-lungs with improved histology and lower resulting creatinine phosphokinase in the treated heart-lungs (Hajjar 1986). HMP was also shown to ameliorate IRI in rat lungs subjected to WI, with replenished energy stores, decreased vascular resistance, increase pulmonary compliance and improved pulmonary oxygenation (Nakajima 2011). The same group showed similar promising results in canine hearts with 2 hour HMP (Steen perfusate) following WI and 12 hour SCS time with elimination of microthrombi histologically, improved energy stores and improved physiologic lung functions (Nakajima 2012).

Although only a small number of medical centers have begun to use lung machine preservation, early results show benefit in conditioning and resuscitation of lung grafts thought to be unsuitable for transplantation. In a study aimed to assess clinical feasibility, high risk lungs were treated with 4 hours of normothermic perfusion and then 20 of 23 high-risk lungs were transplanted, with no difference between these high risk grafts and regular lung grafts transplanted in the same time period (Cypel 2011). NMP was therefore useful in restoration of high risk graft function and a useful tool in the elimination of truly unsuitable grafts. Additionally, lung NMP has been found an effective delivery system for antibiotics and gene therapies to better optimize the fragile grafts for transplantation (Nakajima 2016). One anti-inflammatory cytokine, IL-10 was upregulated by an adenoviral vector delivered through 12 hours of NMP in discarded lung grafts, which resulted in superior arterial oxygen pressure and decreased pulmonary vascular resistance, suggestive of successful lung injury repair (Cypel 2009). Still in its early days, there is a long and promising road ahead for lung machine preservation, reconditioning, and therapeutics.

Pancreatic Machine Preservation

As in the organs mentioned previously, machine perfusion of the pancreas holds promise for decreasing IRI and expanding the donor pool through superior resuscitation of DCD and ECD organs. Historically, HMP of the pancreas has been shown to extend storage times to 24 to 48 hours as compared to SCS (Tersigni 1975). However, machine perfusion of the pancreas, particularly at normal to high pressures, has been associated with edema, congestion and ultimately early venous thrombosis and graft failure, due to the delicacy of the pancreatic vessels (Wright 1990; Karcz 2010). Further research delineated that tight control over arterial pressure in the range of 15–30 mm Hg with UW eliminated endothelial damage and improved graft function (Florack 1983). Difficulty with determining proper settings for pancreatic machine perfusion has been due to research optimizing the wrong endpoints: islet cell yield instead of whole-organ preservation (Barlow 2013). For example, high pressure perfusion resulting in endothelial damage and tissue edema actually improves islet cell yield (Taylor 2010), without improving transplantation outcomes. In addition to sensitivity to perfusion settings, pancreatic perfusion also faces a question of arterial cannulation: splenic or superior mesenteric separately or together.

Recently, pancreatic perfusions preservation has shifted interest from HMP to NMP due to promise in more thorough resuscitation of energy stores, warm ischemic damage, and pancreatic function prior to transplantation. Pancreatic NMP models began as early as 1926 by Babkin and Starling to assess exocrine and endocrine responses (Babkin 1926), and then later as a research model for transplantation following HMP preservation (Pegg 1982). Recent efforts have focused on NMP as a concept for preservation of DCD and ECD livers. However, despite potential benefits of pancreatic MP, the pancreas has proved to be a difficult organ to machine perfuse. Some researchers have attempted *ex vivo* co-perfusion of kidney and pancreas with the kidney functioning as a dialysis organ, hoping for tighter pH control and decreased pancreatic damage, but with limited success (Kuan 2016). The pancreas is particularly susceptible to ischemic damage, both increasing the necessity and relevance of an optimal preservation of DCD livers, but increasing the complexity and physiologic requirements of an *ex-vivo* perfusion system. Insulin production and vascular resistance

during NMP have both been shown to correlate well to pancreatic injury. While there are no current clinical applications, and relatively few animal studies in pancreatic machine perfusion, the technical limitations will likely be overcome in the future in order to expand the number of usable pancreatic allografts.

CONFLICT OF INTEREST

The authors of this chapter have no conflicts of interest to disclose.

SUMMARY

In this chapter, we give a brief overview of the structural and functional aspects of the microcirculation with particular interest in the rheology of microcirculation. A summary of the up-to-date methodology for dynamic observation and quantification of microcirculatory characteristics and hemorheological changes is also given. A special emphasis is put on the applicability of the diverse methodological approaches in different experimental models and human diseases. Finally, we provide highlights of the key findings of vasoregulatory and inflammatory microcirculatory changes as well as rheological alterations seen in local and systemic circulatory disorders in clinically-relevant animal models of human diseases.

Keywords: microcirculatory perfusion, microcirculatory inflammation, hemorheology, methods, key findings

INTRODUCTION

It is noteworthy that most of the cardinal clinical symptoms and signs of inflammation (redness/*rubor*, swelling/*tumor*, increased heat/*calor*, pain/*dolor*, and loss of function/*functio laesa*) can be linked to changes in microcirculation. Due to recent methodological improvements, assessment of the underlying contributory microcirculatory mechanisms has greatly improved in the last decades. Microcirculatory examinations provide not only excellent diagnostic opportunities, but have also been shown to predict clinical outcome and quantitatively express the therapeutic benefits of experimental and clinical interventions.

Microcirculation research is an extremely broad field in the aspects of physiology, pathophysiology, clinical medicine and methodology. Therefore it is challenging attempt to give a detailed outline of these topics. In this chapter, we aimed to overview briefly the morphological and functional aspects of microcirculation, including micro-rheology and a summary of the up-to-date methodology. We also depict some of the major findings and technical aspects of experimental surgical research.

A BRIEF OVERVIEW OF THE STRUCTURE AND FUNCTION OF MICROCIRCULATION

Structure and Function

The microcirculation represents the highest vascular surface of the cardiovascular system consisting of blood vessels with a diameter of $<150\ \mu\text{m}$. The main function of the microcirculation is to deliver oxygen to the cells and maintain tissue oxygenation. Small arteries can give rise to several arterioles as its diameter decreases toward the periphery. Arterioles have an external muscular coat with circumferentially arranged smooth muscle cells while the terminal (precapillary) arterioles (having an internal diameter of 15 to 20 μm)

are surrounded by only one layer of smooth muscle cells. Arterioles show active changes in diameter, and account for a majority of total vascular resistance, therefore the smallest arterioles play a dominant role in the regulation of blood flow. At the level of vessels with the lowest diameter, parenchymal cell lay in close proximity to the capillaries, so that passive diffusion ensures an efficient supply of oxygen to the tissues. Because of the high permeability of the arteriolar and capillary wall to oxygen, the release of oxygen starts from oxyhemoglobin in the red blood cells, a further passing across the capillary wall and the interstitium reaching the mitochondria where it is consumed by its reaction with cytochrome c oxidase. As the endothelial barrier is highly permeable to lipid-soluble and small water-soluble molecules, it ensures the exchange of not only gases, but also nutrients and waste products. In certain tissues such as the mesentery, precapillary sphincters (smooth muscle surrounding the entrance of a capillary) regulate the opening state of the capillary network according to the needs of the tissue segment. Capillaries drain into larger vessels, the postcapillary venules which are the most reactive sites of inflammation within the microvasculature and these veins contain intercellular endothelial junctions that allow transvascular protein exchange and trafficking of circulating cells including leukocytes into the interstitium. Indeed, venules represent the major site of leukocyte trafficking (leukocyte–endothelial cell adhesion). Larger venules that are draining the postcapillary venules, also possess smooth muscle in their media layer (Pries 2003; Pries 2008).

Regulatory Mechanisms in the Microvasculature

Arterioles show dramatic active changes in their diameter, and therefore arterioles account for a majority of total vascular resistance (capillaries and venules accounting for less than 25% of vascular resistance), therefore, the smallest arterioles are mostly liable for the regulation of blood flow under resting conditions. During intense vasodilation, however, this role is shifted toward the larger arterioles (Granger 1988).

Intact microcirculation is characterized by a high proportion of perfused capillaries with low level of flow heterogeneity. Open and closed states of the capillaries generally meet the metabolic needs of the surrounding tissues. Modulation of precapillary sphincters is partly under the influence of systemic factors (i.e., sympathetic stimulation, circulating factors and metabolites), being also dynamically regulated by local factors. In general, regional blood flow is regulated by myogenic, metabolic, and neurohumoral mechanisms. Myogenic autoregulation is the intrinsic ability of a blood vessel to constrict or dilate in response to a change in intraluminal pressure which is further modulated by shear stress-induced release of nitric oxide (NO) (Davis 2008; Davis 2012). According to the metabolic theory of autoregulation, local capillary blood flow meets the metabolic needs of the underlying tissue (Granger 1975).

It appears that there is an important interplay between vascular endothelial cells (EC) and smooth muscle cells. For instance during the phenomenon of endothelium-dependent vasodilation, ECs control the tone of adjacent vascular smooth muscle cells through the production and liberation of vasoactive substances (e.g., NO, prostaglandins, endothelin, ... etc.) and the tone of the blood vessel wall has certain retroactive effect on the activity of ECs (Granger 2010).

Apart from being a selective barrier to fluids and solutes, EC regulate vasomotor tone and exhibit various anti-inflammatory and anti-thrombogenic properties. Intact EC functions are also secured by the endothelial glycocalyx layer which not only separates blood cells from the EC membrane, but also influences local hematocrit, flow, oxygen transport, and interactions between blood cells and the vessel wall (Reitsma 2007). EC activation can be evoked by a variety of chemical stimuli (e.g., cytokines) and physical/shear stress. ECs also play an active role in mediating an inflammatory response. Likewise, an endothelium-mediated vasodilation occurs in response to hypoxia which is mediated by the release of vasodilating prostaglandins and NO (Jackson 1983; Vallet 1994; Vallet 1998; Vallet 2002; Michiels 1993). Similar vasodilatory response is evoked by the release of metabolites (adenosine, lactate, H^+ , and K^+) from the affected tissues (Nakhostine 1993). Neurohumoral modulation depends on vessel size and the distribution of adrenergic receptors within the particular tissue type (Watts 2008). During inflammation, EC activation leads to characteristic alterations in microvascular function (e.g., impaired vasomotor function, thrombus formation, leukocyte adhesion and increased microvascular permeability). During this process, reduction in endothelial glycocalyx thickness and mobilization of endothelium-derived P-selectin from Weibel-Palade bodies occur, causing a rapid initiation of leukocyte rolling, which is followed by a later release of E-selectin (Ley 2007; Langer 2009). These changes contribute to the propagation of the inflammatory response (Aird 2003). A balance between the production of reactive oxygen (superoxide) and nitrogen (NO) species has been implicated in the EC response to inflammation by influencing activating nuclear transcription factors for both pro-inflammatory and anti-inflammatory proteins.

Rheology in Microcirculation

Briefly, the main parameters determining blood viscosity are the plasma viscosity (as the characteristic of suspension fluid), the hematocrit (as the quantity of suspended corpuscle), the red blood cell deformability and aggregation. Main determinants of plasma viscosity are the state of hydration, concentration of large plasma proteins with elongated configuration (especially fibrinogen) and triglyceride level. Hematocrit derives from red blood cell count and mean corpuscular volume (MCV). Factors forming blood cell deformability are absolute cell volume, the surface-volume ratio, cell morphology, intracellular viscosity, cell membrane viscosity and elastic characteristics. Determinants of red blood cell aggregation include composition of plasma as suspension medium macromolecule (mainly fibrinogen concentration), surface features of red blood cells (glycocalyx composition), morphological and mechanical characteristics of the cell and shear rate (Chien 1975; Meiselman 1981; Cokelet 2007a, b; Mohandas 2008; Baskurt 2009; Saldanha 2013).

It is well known that the wall shear rate and the shear stress is the highest in the territory of the microcirculation (Table 1) (McDonald 1974; Lipowsky 1995; Lipowsky 2005; Chandran 2012).

Table 1. Quantitative and morphological data of various vessels types with flow velocity and wall shear rate distribution along the systemic circulatory system (McDonald 1974; Lipowsky 1995; Chandran 2012, Baskurt 2012)

Vessel	Mean diameter [mm]*	Number of vessels*	Mean length [mm]*	Total cross section [cm ²]*	Total volume [mL]*	Percentage of total blood volume [%]*	Mean diameter [mm] #	Mean flow velocity [cm/s] #	Wall shear rate [s ⁻¹] #

Blood and Plasma Viscosity

The blood is non-newtonian, thixotrop and viscoelastic fluid. Blood behaves as a non-newtonian fluid, i.e., its viscosity depends on the shear rate, and can be described by typical Casson-type curves. Non-newtonian characteristics of blood are hematocrit and shear rate dependent. At lower shear rate, the blood viscosity increases (thixotropic effect) due to the viscosity elevating effect of red blood cell aggregation. At higher flow velocity (i.e., higher shear rate), the cells disaggregate and elongate in the direction of the flow due to their deformability and elastic features. This makes the blood viscoelastic. The Maxwell-model serving for its characterization includes reversible elastic deformation and movement connected with the viscous energy (Cokelet 2007b; Chandran 2012).

The connection between *blood viscosity and hematocrit* (Htc) shows exponential rather than linear function ($\log \eta = k + k' \cdot \text{Htc}$, where k and k' are constants characteristic of the blood sample (Cokelet 2007a, b). The hematocrit/viscosity rate presented in the function of the hematocrit shows a connection reminding of a bell-shaped curve, with typical maximum value, which reflects the maximum of oxygen transporting capacity of blood (“optimal” hematocrit), i.e., the most red blood cells possible (the highest hematocrit possible) measured at speed gradient resulting from the lowest viscosity possible (Ernst 1983; Bogar 2005).

Main determining factors of *plasma viscosity* are its water content and the macromolecules with elongated configuration, as the fibrinogen concentration, globulin fractions and triglyceride level are important factors (Harkness 1971; Cokelet 2007b; Kesmarky 2008; Kwaan 2010). It is important to note, that while in several stages of circulation, the apparent viscosity of blood is not constant due to the intravascular interactions and distribution of different shear rate profile and the formed elements, mainly the red blood cells, the intravascular plasma viscosity can be considered constant. So the plasma viscosity maintains shear stress on the endothelium at the cell-poor or sometimes even cell-free zone in the direct vicinity of the ECs (Poiseuille-zone) due to the axial flow profile in vessels with diameter approximately under 300 μm . Moreover, the plasma viscosity provides the shear force in case of the so-called plasma-skimming, when at a certain point and at a certain site, there is no formed element and only plasma in the capillary (Cokelet 2007b; Kesmarky 2008).

Red Blood Cell Deformability

Red blood cell deformability is an ability of passive transformation appearing under the influence of shear stress, and it depends on the absolute volume, surface/volume ratio of the cells, morphological characteristics, viscoelastic properties of the cell membrane and intracellular viscosity (hemoglobin content) (Chien 1975; Meiselman 1981; Cokelet 2007a,b; de Oliveira 2010).

Mature red blood cells of mammals and humans are without nucleus, so the intracellular (cytoplasm) viscosity is mainly determined by the properties of hemoglobin solution. When the mean cell hemoglobin concentration (MCHC) increases above 37 g/dl, the intracellular viscosity increases precipitously, affecting the deformability of the whole cell, and thus also the tissue perfusion and the oxygenation due to impeded passage in the microcirculation. MCHC is regulated within a relatively narrow range (30–35 g/dl), where ATP-dependent Na^+ , K^+ transporters participating in the cell volume regulation play the key roles (Chien 1975; Cokelet 2007b; Mohandas 2008; Baskurt 2012a).

Viscoelastic characteristics of red blood cells are complex (Thurston 2007). Viscosity property derives from membrane viscosity and cytoplasm viscosity. The elasticity feature consists of surface expansion, shearing and bending elements (Thurston 2007; Kim 2012). Surface area expansion (or compression) modulus (K) reflects the stored elastic energy, which develops through isotropic surface expansion or shrinkage of the membrane: $T_t = K (\Delta A/A_0)$, where T_t is the stress force, ΔA is the surface change, A_0 is the original surface. The shear module (μ) expresses the elastic energy which derives from membrane extension at same surface: $T_s = (\mu(\lambda^2 - \lambda^{-2}))/2$, where T_s is the shear stress, λ is the extension rate. Bending (fluxural) modulus (B) expresses the energy which is required for bending the membrane from one curve into another curve: $M = B (C_1 + C_2 - C_0)$, where M is the momentum of bending, C_1 and C_2 are the curves, C_0 is the curve of stress free state (Kim 2012).

Motion of red blood cells can be described in a complex way, depending on the flow conditions; rolling, rotation, swinging, elongation, elastic deformation due to collisions, the combination of all the above, in their hardly modellable complexity. When suspending the cells (such as in plasma) in a low viscosity medium, their motion is similar to that of solids. As the flow rate increases, most of the cells flow along the same path ($C = 0$), where they rotate around their symmetrical axis (perpendicular to the shear level) (Bitbol 1986). If the cells are suspended in a higher viscosity medium over a critical speed-gradient, their behavior

is similar to that of fluid drops. The membrane transmits the momentum towards the cytoplasm, while maintaining the orientation of flow. At low and moderate speed gradient, the biconcave shape of cells remains stable, but at higher values they elongate and gain an ellipsoid shape. Under the effect of pulsatility and in the course of oscillation flow, the inclination angle of the cells is not equal and therefore it becomes chaotic. In smaller veins, especially in the capillaries, the friction has an increased role not only between the cells, but also in the relationship of endothelium and blood cells. The erythrocytes flow in a formation reminding of doughnuts flattened in their middle, where they are the thinnest (Goldsmith 1972; Pries 2003, 2008; Popel 2005; Dupire 2012).

Therefore, the deformability participates to a different extent in the different stages of circulation. Worsening deformability, i.e., the enhanced rigidity of red blood cells, in the mass flow zone of circulation (vessel diameter $>300\text{ }\mu\text{m}$) may lead to elevated blood viscosity. Red blood cells with reduced deformability can cause the most significant problem in the microcirculation (vessel diameter $<100\text{ }\mu\text{m}$), more precisely in the zone of so-called individual flow. Here, capillaries with diameter of $3\text{--}5\text{ }\mu\text{m}$ may also occur, not to mention the fenestration through the red pulp of the spleen to gaps of even smaller diameter. For passing through these capillaries, the appropriate deformability is essential.

Red Blood Cell Aggregation

Erythrocyte aggregation means the reversible connection of cells which happens at low shear rate or during stasis. Red blood cells initially arrange next to each other in a rouleaux formation, resembling a stack of coins. It takes place within few seconds: the simpler rouleaux form in 1–5 seconds. Over a period of further 10 to 60 seconds arranging in a two- then three-dimensional shape until the effects maintaining the aggregation are present (Baskurt 2012a). In anticoagulated blood samples, the aggregates coagulate into larger balls, then due to the gravity, start to sink. This provides the background of the erythrocyte sedimentation rate (ESR), since if the aggregation is fast and/or extensive, the erythrocyte sedimentation will also be more intensive (Hardeman 2007).

The process of red blood cell aggregation is not yet completely clear. At present there are two model theories to explain the aggregation development. (1) The aggregation of red blood cells approaching each other happens via non-covalent cross-connections of macromolecules (large proteins with elongated structure, such as fibrinogen, or *in vitro* with different polymers) (*bridging model*). This weak linkage dissolves as the disaggregation forces such as the electrostatic repulsion (due to negative charge, zeta potential: -15.7 mV), membrane tension, deformation and mechanical shear stress prevail (the aggregates can be completely dispersed at above $20\text{--}40\text{ s}^{-1}$ shear rate). This model supposes that the protein or polymer concentration is high on the cell surface. Absorbing macromolecules non-specifically binding to cell surface structures through their size and quantity may compensate the electrostatic repulsion, facilitating the aggregation. (2) According to the other explanation, the macromolecules are not able to penetrate as far as the membrane just because of the glycocalyx structure of cell surface ($5\text{--}50\text{ nm}$), therefore close to the cell surface, a layer deficient in macromolecules or depletion zone develops (*depletion model*). As two red blood cells approach each other, due to the osmotic gradient between the macromolecule concentration being in plasma phase and the depletion zone, a “pulling” force may develop, which makes the aggregation. The higher is the macromolecule concentration, the more

intensive may this gradient be, causing enhanced aggregation (Baskurt 2012a; Saldanha 2013).

There is no unambiguous opinion pro or contra the absolute justification of the two theories, though most of the evidences promote the depletion model. However, the existence of direct intercellular or even cross-binding connections cannot be excluded. Carvalho et al. analyzed structures similar to $\alpha_{IIb}\beta_3$ glycoprotein complexes existing on platelets' surface, facilitating the direct binding of fibrinogen also in red blood cells by their spectroscopy techniques based on atomic-force microscopy. These receptors existing also in the erythrocytes, have lower affinity than that of platelets, the receptor-fibrinogen binding can be broken-up with less energy (Carvalho 2010). Is it possible that both models are true together? Depletion energies are essential for the "allurement" of the cells, and when in this situation, they are close to each other and real cross-binding may develop? No univocal explanation of this hypothesis exists so far.

It is a fact that various plasma proteins, and *in vitro* the polymers with different molecular size influence the development of aggregation process, and to a different degree. Red blood cell aggregability studies indicate that aggregation ability is influenced by cellular factors and is independent from the properties of the plasma (Baskurt 2012a). Aggregability can be measured comparatively *in vitro* in various macromolecule solutions. It has been proved that from the plasma proteins, fibrinogen, C-reactive protein and immunoglobulin M have the effects of facilitating and enhancing red blood cell aggregation. Further, immunoglobulin G and haptoglobin show rather increasing effect, while transferrin, coaguloplasmin and albumin do not influence erythrocyte aggregation (Baskurt 2012a; Saldanha 2013). *In vitro* the high molecular weight macromolecules and polymers such as 60 or 73 kDa dextran, or the 360 kDa polyvinylpyrrolidone (PVP), and the 36kDa polyethylen-glycol (PEG) promote/enable red blood cell aggregation, but their versions with lower kDa have no effect on the aggregation (e.g., PEG 10, 10.5 or 18.1 kDa dextran). Armstrong et al. stated that if hydrodynamic radius of macromolecules or polymers is more than 4 μ m, they have an effect of enhancing the aggregation; if it is less than 4 μ m, they do not influence the aggregation (Armstrong 2004).

When there are few red blood cells in a certain area, where other conditions of aggregation are normally available, they have less chance to get close to each other. Therefore, the aggregation depends on the hematocrit as well: the aggregation index (AI, which increases by the extent of aggregation) shows nearly linear connection, positive correlation between 20–40% Htc, between 40–50% Htc the curve is less precipitous, while between 50–60%, the AI does not change significantly by (adding) a unit of Htc (Baskurt 2012a).

For the aggregation to occur, the existence of biconcave cell form is crucial. Ovalocyte, spherocyte, echinocyte, sphero-echinocyte cell forms are not or less capable to aggregate. During the aggregation, according to the principle of the least energy loss, the process is going towards the binding on the maximal surface. That is why biconcave form is advantageous, and that is why rouleaux formation develops relatively quickly and then from these with the terminal and side connections geometrical shapes having smaller surface (Reinhart 1980; Meiselman 1981).

All in all, the process and extent of the aggregation depends on the shear rate, concentration of plasma fibrinogen, hematocrit and on cellular properties, like cell surface glycocalyx composition of red blood cells (type of depletion zone, glycoproteins enabling possible direct connections), and the formal characteristics of the cell (biconcave form). All

these can vary in a very complex way in different diseases, pathological states, and it also provides a background to a great diversity in the comparison of mammalian species and the human.

Micro-Rheology and Microcirculation

Fåhræus observed in 1958, that by enhanced aggregation, the axial flow in the glass capillary ($d = 95 \mu\text{m}$, flow rate = 3.3 mm/s) i.e., the aggregation of red blood cells along the flow axis is more expressed and the cell-free side zone is wider. The parabolic flow rate profile developing due to the laminar flow and the presence of circulating particles (blood cells) dimming it to some extent, creates the phenomenon typically appearing in the range under $200\text{--}300 \mu\text{m}$ vein diameter, the axial migration of red blood cells (Figure 1). It means that within the vein's cross section, the distribution and velocity of red blood cells are not even, which leads to the dynamic reduction of hematocrit, to the Fåhræus-effect. Below approximately $30 \mu\text{m}$ diameter, down to about $10 \mu\text{m}$, the apparent blood viscosity decreases with the diameter (Fåhræus-Lindqvist effect) (Fahraeus 1931). Along the vessel wall, a side plasma zone deficient of red blood cells develops or being even cell-free (Poiseuille-zone), which reduces the friction, hereby the hydrodynamic resistance between the vascular wall and the flowing fluid. If the flow rate is high enough, every formed element aggregates towards the flow axis. When the speed gradient and pressure conditions enable the development of red blood cell aggregation (typically in the area of postcapillary venules and venules), the size of particles (aggregates) flowing along the axis increases, the Poiseuille-zone widens, also facilitating the margination of white blood cells (Bishop 2001; Baskurt 2008; Nash 2008) (Figure 1).

In the microcirculation approaching the individual flow stage (capillaries) due to the extremely variable ramifications, connections, bends, endothelial surface features, red blood cell distribution, the tissue hematocrit is highly variable (Wells 1964; Lipowsky 2005; Popel 2005; Pries 2008).

Figure 1. Schematic drawing of the circulatory pattern in vessels with diameter $<100 \mu\text{m}$. Due to the parabolic flow velocity profile (the flow speeds up along the axis of the vessel), the axial migration of red blood cells occur. In the vicinity of the endothelium, the cell-poor/cell-free plasma zone, the Poiseuille-zone is formed, allowing room for leukocytes. Increased red blood cell aggregation makes the axial flow more expressed with widening Poiseuille zone, driving the leukocyte tethering, margination, and also slowing down their rolling (based on Baskurt 2008; Nash 2008; Yalcin 2011).

Table 2. Brief overview of the available methodology for the detection of functional characteristics of the microvasculature

Method	Species/tissue	Parameters	Indications	Limitations	Reference
Nailfold videocapillaroscopy	human/nailfold	Capillary distribution (density), morphological abnormalities, blood velocity,	chronic diseases (diabetes, vasculitis, arteritis)	Only human application	Awan 2010

Several other factors should be considered to better understand circulation conditions in the field of microcirculation such as the extremely variable microvascular network geometry. The vessel cross section can almost never be described as a regular circle. Elasticity of vessel wall, hemodynamic features, flow profile and parameters (e.g., Reynolds number, Womersley number) have to be taken into consideration as well (Pries 2008; Chandran 2012). Thus, *in vivo* models have a great significance in further studying the connection of hemorheological factors and microcirculatory characteristics, which can provide simultaneous data on most of the above parameters.

So, the microcirculation possesses characteristic micro-hemodynamic features. Due to the decreasing size of the microvessels, the major pressure drop occurs in the first-order arterioles (based on the Hagen-Poiseuille equation), therefore constriction status of these vessels has the highest influence on the regional flow. Local capillary flow, however, is controlled by third-order, small-sized terminal arterioles. Efficacy of perfusion can be termed by a parameter called the “functional capillary density” (FCD) which reflects the length of perfused capillaries within a given area (Honig 1982). Reduced FCD results in a reduced surface area for capillary exchange and an increase in diffusion distance (Hepple 2000). Recruitment of capillaries depends on morphological features of vessels/endothelium of the given region and also on blood rheology factors (i.e., hematocrit, viscosity, blood cell deformability and aggregation), cellular factors, immune function, and coagulation function). Deterioration of microcirculatory perfusion is marker of severity for many forms of circulatory disorders such as hemorrhagic, cardiogenic, and septic shock, also reflecting the outcome of the disease (Sakr 2004; Fang 2006; den Uil 2010). Hence, microcirculation might be considered an important prognostic indicator in different clinical scenarios.

METHODS FOR DYNAMIC EXAMINATION OF MICROCIRCULATORY FUNCTIONS

There are numerous invasive and non-invasive methods for investigating the microcirculation. The limitation of this chapter does not allow to overview all the methods and their developments in details. Table 2 gives a brief overview of the currently available methodology for the detection of functional characteristics of the microvasculature.

Videomicroscopic Techniques

Direct visualization of the microcirculation with different types of *in vivo* microscopic methods (IVM) enables not only examination of the architecture of arterioles, capillaries and venules, but also provides an opportunity for continuous detection and quantification of dynamic functional changes. Apart from nailfold capillaroscopy, most organs can be reached via surgical exposure of the tissues for IVM examinations. Using meticulous microsurgical techniques, an access of the microscope objectives and the required tissue depth can be achieved by maintaining the proper physiological conditions without causing any disturbance of the patency of the microcirculation. Because of optical consideration (limited penetration of light into the tissue, scattering), limited depth for examination of the tissue is a

characteristic feature of IVM methodology. For this reason, an appropriate imaging modality enabling examination of the required tissue depth should be chosen for all experimental studies. By these methods, the dynamics of microcirculatory environment can be assessed over time and space with the required resolution closely approximating the natural microcirculatory environment.

Nailfold Videocapillaroscopy

This non-invasive technique involves a conventional light microscope combined with a video camera and a recording system. It is suitable for the evaluation of capillary density, morphological abnormalities and blood flow in the nailfold area (Awan 2010). Main indications: chronic diseases such as diabetes, vasculitis and arteritis

Fluorescence Intravital Microscopy

In the earliest studies, bright-field transillumination of relatively translucent tissues was employed (Hoole 1800; Wagner 1839), but trans- and epi-illumination techniques (with microsurgical exposure of the tissue of interest) and the use of incident ultraviolet illumination and its combination with specific fluorescence tracers enabled observation of individual cells and cell-vessel wall interactions in later IVM studies (Ellinger 1929; Irwin 1953; Zweifach 1954; Reese 1960; Menger 1991). Epifluorescence microscopy has enabled detection of the dynamics of individual cells within the microcirculation (Endrich 1980). The spatial resolution has been further improved by the use of confocal microscopy (Villringer 1989), but these techniques still resolve structures 100–200 micrometers below the organ surface. By using the combination of IVM with high-resolution video recordings and an off-line analysis, dynamic microcirculatory processes could be analyzed in sufficient details (Menger 1991).

Due to atraumatic microsurgical techniques in experimental settings, almost all organs and tissues could be reached for IVM examinations (brain: Rovainen 1993; spine: Ishikawa 1999, heart: Tillmanns 1974, lung: Kuhnle 1993, liver: Menger 1991, pancreas: Klar 1990, intestine: Bohlen 1978, kidney: Steinhausen 1981, lymph nodes: von Andrian 1996, and bone marrow: Mazo 1998). A large range of vascular, cellular and molecular functions can be assessed by using specific fluorescent markers. Specifically, individual microvessels (from 3–5 μm in diameter), plasma, red blood cells, platelets and circulating immune cells can be visualized (Table 3, Figure 2).

The widefield fluorescence IVM methodology was advanced to the laser scanning confocal technology, two- and multiphoton and spinning disk microscopy, which made deep tissue imaging (at a single cell as well as subcellular level) also possible (Denk 1990; Zipfel 2003; for review see Pittet 2011 and Masedunskas 2012). Clinical applications of the new imaging technologies such as laser endomicroscopy have made *in vivo* real-time microscopic imaging and diagnostics also possible (Paramsothy 2010).

Table 3. Most common fluorescence labeling techniques used in fluorescence IVM studies

Targets	Fluorescence markers	Derived microcirculatory parameters	References
Red blood cells	FITC	red blood cell velocity, blood flow, functional capillary density	Ruh 1998
PMNs	Rhodamine 6G, Acridin orange	PMN-endothelial interactions	Saetzler 1997; Massberg 1998
Platelets	Rhodamine 6G (ex vivo)	platelet-PMN-endothelial interactions	Massberg 1998
Plasma (or plasma proteins)	FITC-dextran (40-2000 kDa)	microvascular permeability	Persson 1985
	tetramethylrhodamine-labelled BSA	microvascular permeability	von Dobschuetz 2004 Egawa 2013
	FITC-albumin	microvascular permeability (two-photon IVM)	
Hepatocytes	Rhodamine 123	mitochondrial membrane potential	Sun 2001
Hepatocytes	NADH autofluorescence	mitochondrial respiration	Roesner 2006
Kupffer cells	non-occluding fluorescent beads	Kupffer cell activation	Watanabe 2007

PMN: polymorphonuclear leukocytes, FITC (fluorescein-isothiocyanate), BSA (bovine serum albumin),

OPS-SDF-IDF Techniques

Using these methods, microvessels can be observed via visualization of their hemoglobin-containing red blood cell content. By means of epi-illumination of superficial tissue layers (up to 2–3 mm in depth) with polarized light (Groner 1999) or incident light (Goedhart 2007), photons are reflected from the deeper tissue parts, providing illumination of the superficial layers. As the reflected-scattered light is absorbed by hemoglobin (at the isobestic point oxygenated and deoxygenated hemoglobin of 530 nm wavelength) within the red blood cells, they appear as black or grey points flowing along the vessels (Groner 1999; Goedhart 2007; Leahy 2012; Lehmann 2012).

The orthogonal polarization spectral (OPS) imaging device (Cytometrics, Philadelphia, PA, USA) uses linearly polarized green light source to illuminate the tissue. The reflected polarized light is blocked by an orthogonally polarized analyzer, while depolarized scattered light can pass through to the camera (providing a dark-field image). The OPS imaging was introduced by Groner et al. in 1999, which was followed by the more advanced Sidestream Dark-Field (SDF) imaging in 2007, introduced by Goedhart (produced by the Microvision Medical B.V., Amsterdam, the Netherlands; the device being called Microscan) (Goedhart 2007; Milstein 2012). Another SDF system (CapiScope HVCS) is produced by KK Technology (Honiton, UK) (reviewed by Massey 2016). Microscan and CapiScope HVCS have similar image size (720×480 and 752×480 pixels, respectively) and resolution (1.45×1.58 and $0.92 \times 0.92 \mu\text{m}/\text{pixel}$, respectively). An improved version of the latter one is the Capiscope HVCS-HR which has higher resolution ($0.81 \times 0.81 \mu\text{m}/\text{pixel}$). The newest generation of videocapillaroscopy is based on the incident dark field (IDF) principle (Braedius Scientific™) (Hernandez 2013). Recently, a new device based similarly on IDF imaging (Cytocam) was developed with improved optical lenses, a high-resolution ($0.66 \times 0.66 \mu\text{m}/\text{pixel}$) computer-controlled image sensor, higher image size (2208×1648 pixels),

and with an application for automatic data analysis (Aykut 2015; van Elteren 2015; Gilbert-Kawai 2016).

Figure 2. Representative micrographs showing the intestine and the liver with conventional fluorescence IVM (A-C, E, H), OPS (D, G) and laser scanning confocal microscopy (F, I). FITC-labeled red blood cells (A), plasma labeling (B) and rhodamine 6G-labeled leukocytes in the longitudinal muscle layer of the rat ileum (C); OPS images of the intestinal villi (D) and liver hepatic sinusoids (G) in Sprague-Dawley rats. FITC labeling of the microvessels in the intestinal villi in BALB/c mice as detected with fluorescence IVM (E) and in the intestinal villi (F) and the liver (I) in rats using laser scanning confocal microscopy. Bar denotes 100 μ m.

The IVM images were taken by using a Zeiss Axiotech Vario 100HD IVM microscope, 100W HBO mercury lamp, Acroplan 20 $\times$ water immersion objective, Carl Zeiss GmbH, Jena, Germany) and a CCD camera (Teli CS8320Bi, Toshiba Teli Corporation, Osaka, Japan). The OPS images were taken by the Cytoscan A/R device (Cytometrics, Philadelphia, PA, USA). (Original recordings of AS).

As these hand-held microscopes do not require any dye and allow for non-invasive visualization of the microcirculation in patients particularly in the oral cavity. For analysis of microcirculation with SDF/IDF devices, De Backer et al. have proposed the use of the following parameters: proportion of perfused vessels (PPV), perfused vessel density, microvascular flow index (MFI), and heterogeneity index (De Backer 2007). Further approaches together with those used in conventional fluorescence IVM are summarized in Table 4.

**Table 4. Commonly used parameters for different IVM methods
(partially based on ref. by Massey 2016)**

Parameter	Definition	Method where the parameter is used	Reference
Red blood cell (or plasma) velocity (RBCV) ($\mu\text{m/s}$)	Velocity of red blood cells or plasma	conventional fluorescence IVM, OPS, SDF, IDF	Lehr 1993; Groner 1999
Total vessel density (mm/mm^2)	Total length of vessels is divided by the total surface of the analyzed area	conventional fluorescence IVM, OPS, SDF, IDF	Donati 2013; Bezemer 2008
Functional capillary density (FCD) (mm/mm^2)	Total length of capillaries with red blood cell flow referred to the observation area	conventional fluorescence IVM, OPS, SDF, IDF	Lehr 1993; Groner 1999
Functional vessel density #1 (mm/mm^2)	Total length of perfused vessels (sluggish or continuous) referred to the observation area	OPS, SDF, IDF	Donati 2013
De Backer score (vessel density) (1/mm)	Calculated based on the line crossing method when the image is divided by three vertical and three horizontal lines. This score is calculated as the number of vessels crossing the lines divided by the total length of the lines.	SDF, IDF	De Backer 2007; Donati 2013, Bezemer 2008, Sakr 2010
Microvascular flow index (MFI) (arbitrary units)	Based on flow characterization (absent, intermittent, sluggish or normal) of vessels using the line crossing method (in four quadrants of the recorded images) An average of the scores is used.	SDF, IDF	De Backer 2007, Donati 2013, Bezemer 2008
Proportion of perfused vessels for large vessels (PPVI) (%)	$100 \times$ number of perfused vessels divided by the total number of vessels	IVM, OPS, SDF, IDF	Donati 2013, Bezemer 2008, Sakr 2010
Proportion of perfused vessels (length) (PPV) (%)	$100 \times$ length of perfused vessels divided by the total length of vessels	conventional fluorescence IVM, OPS, SDF, IDF	De Backer 2007
Perfused vessel density #2 (1/mm)	Vessel density $\times$ PPV	SDF, IDF	Bezemer 2008
Flow heterogeneity index	The difference between highest and the lowest MFI is divided by the mean flow velocity	SDF, IDF	De Backer 2007, Donati 2013
PMN rolling (defined as rodamine 6G-labeled cells moving at a velocity less than 40% of that of the erythrocytes in the centerline of the microvessel) (1/mm/s or % of total PMNs)	The number of rolling cells divided by the vessel circumference	conventional fluorescence IVM	Lehr 1993, Bajory 2002
PMN adhesion (cells that did not move or detach from the endothelial lining within an observation period of 30 s) (1/mm ²)	The number of cells divided by mm ² of endothelial surface	conventional fluorescence IVM	Lehr 1993

Laser Doppler Flowmetry

The background of laser Doppler monitoring is the “Doppler shift” phenomenon (Doppler 1942). When a monochromatic laser light enters the tissues and meets moving blood cells, it undergoes changes in wavelength (Doppler shift), but remains unchanged if the beam of light hits static tissue structures. Magnitude and frequency changes of wavelength correlate with the number of moving blood cells (Stern 1975). The Doppler technique provides “perfusion units” which cannot be transformed in terms of flow (e.g., ml/min), but rather a flux unit without dimension, since it is an integral over the velocity and the number of moving red blood cells in the tissue territory laying under the probe (Obeid 1990; Leahy 1999, 2012; Friedriksson 2012;).

There are two major approaches of perfusion measurements, the laser Doppler perfusion monitoring and laser Doppler perfusion imaging (Rajan 2009; Friedriksson 2012; Leahy 2012).

Laser Doppler Perfusion Monitoring

In this one-point measurement method, a fiber-optic probe is used to deliver the laser light to the tissue, and another fiber to detect the back-scattered photons recording the integrated perfusion in a sampling volume in real time. The measurement depth and sampling volume depend on the wavelength (usually 630, 780 and 830 nm are used) and the fiber separation used. In the skin, (using 780 nm wavelength), the measuring depth is 0.5–1 mm and the measurement volume is approximately 1 mm³. The main manufacturers of laser Doppler instruments are Perimed AB (Stockholm, Sweden), Moor Instruments Ltd. (Axminster, UK), Transonic Systems Inc. (Ithaca, New York, USA), Oxford Optronix Ltd (Oxford, UK) and LEA Medizintechnik (Giessen, Germany).

Laser Doppler tissue flowmetry method can be widely applied both in the clinical and research work to study local or systemic effect of heat, reflex vasodilation, microcirculatory changes following occlusion, or the effects of vasoactive drugs, as well as endothelial reactivity using provocation tests (ischemia, heat) (Obeid 1990; Nevieri 1996; Rajan 2009; Friedriksson 2012; Leahy 2012).

However, numerous factors may influence the results. This method considerably and sensitively indicates the changes occurring in microcirculation, but at the same time, several factors may influence the measurements. These factors on one hand include the thickness of the examined tissue, its anatomical structure, optical properties (pigmentation), possible morphological alteration and vascularity. On the other hand, from the patient’s side, the gender, age, hormonal and neurological effects and drugs may affect the results of the measurement. From the side of the device, the displacement and contamination of the probe, kinking of fiber optics, distance of emission and receiving optical fibers, wavelength of laser light and biological zero signal may also be considered as influencing factors. Disturbing artifacts or “noises” may develop through the movement of optic fiber or from the affected tissue (e.g., breathing, intestinal peristalsis). External factors such as temperature, humidity, air movement also influence the measurement; therefore, it is very important to ensure standard circumstances. However, performing comparative studies (e.g., before and after intervention) is difficult, because to ensure the same conditions in all parameters is almost

impossible (Obeid 1990; Neviere 1996; Nemeth 2003; Rajan 2009; Friedriksson 2012; Leahy 2012).

In pathophysiological processes—such as sepsis or ischemia-reperfusion— associated with acute changes of tissue microcirculation, laser Doppler technique is highly justified. In experimental models, probes available in various versions can be applied in several ways (Nemeth 2003; Rajan 2009; Friedriksson 2012; Leahy 2012):

- probe touched directly to the surface of skin or in open surgery of the organ (manual or preferred trestle fixing)
- probe fixed on the surface of the organ (stitches)
- in laparoscopy introduced via trocar and touched to the surface of examined intraperitoneal organ or the peritoneum
- introduced in endoscopy and touched to the surface of mucosa (multichannel endoscopy, fiber optic probe)
- implanted between tissue layers or bone mortise for monitoring

Depending on the wavelength of the applied laser, the depth of the tissue area that can be examined may range from 0.1 to 0.8 mm, e.g., by applying laser with 780 nm wavelength and probe with 0.5 mm diameter, this tissue depth is 0.73 mm in muscles, 0.52 mm in the liver and 0.5 mm in the skin. The duration of the examination and positioning of probe should be taken into consideration. The 0.5 mW energy derives from laser light, and in the examined tissue, it may also influence the state of capillaries after some time (Friedriksson 2012).

The probe stabilization is essential. Overpressure of the tissues may cause local microcirculatory disturbance; if too loose, displacing or fixing may lead to inaccurate measurements and several artifacts.

Several solutions are known for the right interpretation of the recorded signal in the literature. For instance, the native values measured and assessed at a certain interval by the device can be used. Within this interval (e.g., data of stable signal over 10 or 20 seconds), the values can be averaged. Relative changes compared to initial values, moving average, Fourier transformation and various timeline analysis methods can also be used for analyzing laser Doppler recordings (Obeid 1990; Nemeth 2003, 2014b; Rajan 2009; Friedriksson 2012; Leahy 2012).

An organ may show different laser Doppler signals with different recorded patterns depending on the functional and morphological state of microvasculature. Therefore, it is important to observe the characteristics of the recorded signal and decide how to analyze and interpret the data. Signals recorded in skin, liver, kidney and muscles vary within a relatively small range, but they are never consistent. In other organs such as bowel, omentum or pancreas, the signals oscillate between wider ranges, so the averaging is difficult in these cases; it may even be misleading if we analyze a data set of an inadequate period with their extremes (Nemeth 2003, 2014b).

During a prolonged monitoring, when the probe of the device is fixed in a steady, permanent position and the microcirculation is being monitored for half an hour or even longer, the extent and dynamics of changes can be analyzed separately. This point of view is of particular importance in examinations which aim to follow organic microcirculatory effects of different materials and surgical maneuvers.

Regarding the several factors which influence the measured values, examining the changes in correlation with the baseline values is an extremely useful data analyzing method. Thus it can be expressed as a percentage to what extent a certain tissue area changes during a surgery. It is a very important point to indicate baseline value, as it was mentioned, intensity of laser Doppler signal is not constant in any of the tissue areas, more or less irregularities, periodicity and artifacts appear. Should we use any data analysis and interpretation method, it has to be consistent and standardized.

Laser Doppler Perfusion Imaging (Laser Doppler Scanner Technology)

A laser Doppler perfusion imaging technology maps the perfusion from a larger area by scanning the laser beam over the area of interest without having any direct contact with the tissues (Essex 1991; Fredriksson 2012; Steenbergen 2012 a, b). These instruments provide perfusion map of an area with a (normally) heterogeneous perfusion and also gives the average of perfusion of the examined area in a single measurement. The main manufacturers of laser Doppler perfusion imagers are Perimed AB and Moor Instruments Ltd. Using stepwise changes in the illuminating laser beam wavelength or different wavelength simultaneously, the spatial resolution can be increased up to 0.1 mm.

Laser Doppler Flowmetry Combined with Reflectance Spectrometry

The more recent technology (the O2C device, Lea, Giessen, Germany) combines the laser Doppler technique and reflection spectroscopy. Using specific probes, white light (wavelengths 500–800 nm) and laser light (wavelength 830 nm) are introduced simultaneously. The absorbed portion of the light spectrum is absorbed on erythrocytes assuming the color of the hemoglobin as measured by oxygen saturation, while laser light reflects perfusion (based on the Doppler shift). The sum of all erythrocytes and their velocity provides a measure of blood flow (volume flow). The following parameters can be measured simultaneously with this technology: oxygen saturation of hemoglobin at the venous end of the capillaries, regional amount of hemoglobin as a measure of blood volume and capillary density, velocity and flow of the blood within the microcirculation. This method has been employed to assess the microvascular response in patients with septic shock (Sakr 2004; Sakr 2010) and in anemia (Menzebach 2008), to estimate flap viability (Hölzle 2010) and wound healing in burn injury (Merz 2010).

Laser Speckle Imaging

A speckle image is created when an object is illuminated by laser light. The backscattered light will form a random interference pattern consisting of dark and bright areas (speckle pattern). In case of a moving object (e.g., red blood cells) in the underlying tissue, the speckle pattern changes over time depending on the extent of movements within the examined area. As a result, the level of blurring differs resulting in various extent of speckle contrast (Briers 1999; Briers 2012; Boas 2010; Steenbergen 2012b). Consequently, changes in microcirculatory perfusion characteristics under a surface (within a typical depth range of 1–5

mm, max. 15 mm) can be analyzed. The resolution depends on the characteristics of detector as well as the size of examined surface and the distance of the detector. Using this method, preclinical and clinical detection of the skin (Choi 2004; Rege 2011; Sandker 2014) and even cerebral blood flow (Parthasarathy 2010; Qin 2012) could be performed.

It was recently demonstrated that the distribution of blood flow within tissue beds can noninvasively be visualized also by the motion-contrast laser speckle imaging which leads to enhanced visibility of distinct vascular beds, including capillaries (Liu 2013).

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) is a non-invasive technique that assesses the redox state of microcirculatory hemoglobin by measuring oxyhemoglobin, deoxyhemoglobin, total hemoglobin and other chromophores (myoglobin, cytochrome aa3) in mostly the venous system (De Blasi 1994; Pareznik 2006). Vascular occlusion tests allow quantification of the rate of decay of microcirculatory oxygen saturation thus representing the metabolic status of the underlying tissue (muscle) (De Blasi 2008).

Measurements of O₂ Tension and Saturation

Conventional oximetry (hemoglobin oxygen saturation measurement) is widely used in the clinical practice and is based on the assessment of differences in the absorption spectra of oxy- and deoxy-hemoglobin. Interestingly, it was first applied *in vivo* within the microcirculation to obtain oxygen saturation in single vessels using IVM (Pittman 1975; Pittman 2013). Transcutaneous arterial oxygen pressures can simultaneously be measured using standard pulseoximetry, whereas transcutaneous venous carbon monoxide tensions with CO₂-sensitive electrodes (Fromy 1997).

Phosphorescence quenching microscopy is based on the collisional quenching phenomenon which occurs when excited phosphor decays back to the ground state by emitting a photon (phosphorescence) or by transferring energy to nearby oxygen molecules. This enables measurements of the O₂ tensions (Vinogradov 2002). The energy transfer to oxygen results in the formation of the reactive species singlet oxygen, which can then react with nearby organic molecules, thereby resulting in the consumption of the original oxygen molecule.

Oxygen tensions in the microcirculation can be measured using oxygen-sensitive polarographic microcathodes (Buerk 2004). Oxygen saturation can also be non-invasively measured using the Resonance Raman microspectroscopy (Ward 2006). The phosphorescence quenching approach (Vinogradov 2002) and oxygen electrodes (Buerk 2004) can also measure oxygen tensions in the interstitium.

***In vivo* Measurements of Mitochondrial Functions and Oxygen Tensions**

The “Protoporphyrin IX–Triplet State Lifetime Technique” is a new approach developed for the measurement of mitochondrial function and oxygen tension (mitoPO₂) *in vivo* (Mik

2006, Harms 2015). A recently developed non-invasive technique is able to measure a decline in mitoPO₂ after pressure-induced cessation of blood supply (called oxygen disappearance rate), also providing estimates of mitochondrial oxygen consumption. The oxygenation data was validated in a sepsis study in rats with the use of reflectance spectroscopy (combined laser Doppler) in the skin. They also demonstrated the feasibility of the non-invasive technology to assess mitochondrial function in the human skin.

Further Methods

Due to the limitations of the chapter, further special methods are just briefly summarized, referring to detailed handbooks (e.g., Leahy 2012).

Subsurface Spectroscopy (Tissue Viability Imaging)

For tissue viability imaging (TiVi), further possibilities are based on wideband spectroscopy of backscattered light (subsurface spectroscopy) for mapping local red blood cell concentration. The sequential photo recordings are being analyzed by a software package, allowing studies of dynamic skin reactions (using agent or effects that cause vasodilatation or vasoconstriction) (O'Doherty 2012).

Optical Microangiography

Because of the high spatiotemporal resolution and the small dimension, microvasculature imaging is technologically challenging. Optical microangiography (OMAG) is capable of resolving three-dimensional distribution of dynamic blood perfusion by imaging the endogenous light scattering from moving red blood cells. The technique is based on Fourier domain optical coherence tomography (FDOCT) (Wang 2012).

Photoacoustic Tomography

Photoacoustic tomography (PAT) detects endogenous or exogenous optical absorption contrast acoustically. When red blood cells are irradiated by a short-pulsed laser beam, a transient thermoelastic expansion occurs that induces high-frequency ultrasonic (photoacoustic) waves. The device encodes the red blood cell distribution and makes a reconstruction of a three-dimensional microvascular image. Using multi-wavelength measurements, differentiation of oxyhemoglobin and deoxyhemoglobin is also possible. Based on PAT, photoacoustic microscopy (PAM) and photoacoustic computed tomography (PACT) methods are known (Hu 2012).

High Frequency Ultrasound Imaging

Maximal imaging frequency of clinical ultrasound systems are typically 12–15 MHz, providing resolution on structures of $>300\ \mu\text{m}$. The micro-ultrasound devices (preclinical imaging) have been developed for the range of 15–80 MHz (Foster 2012).

Micro-CT, Nano-SPECT-CT, NMR

Micro-computed tomography (Micro-CT) is a powerful tool to study small animals, corrosion specimens or biopsies. The resolution of Micro-CT is about 1–100 μm in rotating state, ~ 50 –100 μm in rotating scanner in plane. Micro-SPECT and micro-PET resolution is about 1–2 mm, while micro-magnetic resonance imaging (MRI) provides a resolution about 100–200 μm in plane and ~ 0.5 –10 mm slice thickness (Kline 2012). Boundaries of the nuclear magnetic response imaging (NMRI) techniques and applications (MR angiography, MR perfusion imaging, functional MRI) widen, providing more possibilities to investigate structural and functional state of the vasculature as well (Kerskens 2012).

BRIEF OVERVIEW ON METHODS FOR ASSESSMENT OF RHEOLOGICAL PARAMETERS

Methods for Measuring Blood and Plasma Viscosity

For the determination of blood viscosity, only those measuring devices are suitable, which can determine viscosity at different shear rates (Cokelet 2007a, b). The shearing tension or speed gradient profile may be generated under the effect of gravitational force (e.g., in capillary viscometers), or through rotational motion with a certain angular velocity, produced by a built-in mechanism (rotational viscometers) (Baskurt 2009).

Most of the viscometers were the capillary type until the 1960s, rotational viscometers appeared later. In the capillary-type ones, the flow rate profile can be determined from the position-time data of fluid column, and the shearing tension can be calculated from the geometry of tube. The geometry of rotational viscometers can be various: cone-plate, cone-in-cone or coaxial cylinder (or Couette-system) in speed-gradient controlled or shearing tension controlled form. The fluid to be measured can be filled in between the two elements (e.g., ‘bob’ and ‘cup’). One element can be rotated by adjusted angular velocity. The torque relocated to the non-rotated element to an extent is depending on the viscosity of the fluid. The torque is tested by laser reflection, and the viscosity can be calculated at a certain shear rate-gradient. Oscillation flow viscometers are also known, which are suitable for the investigation of viscous and elastic components. The viscous component can be calculated from the amplitude of speed gradient, and the elastic component is calculated from phase delay of shearing tension in relation to the speed gradient (Rosencranz 2006; Hardeman 2007).

For the measurement of plasma viscosity—based on the newtonian characteristics—viscometers, whose method does not depend on shear rate gradient, are suitable. The dynamic

viscosity of the fluid can be calculated from fluid flow rate in a system with a certain geometry, from position-time data (U-tube or capillary viscometers: e.g., Ostwald, Coulter-Harkness, Rheomed, Luckham viscometers), or in the falling ball viscometers (e.g., Haake-type) from the effect of drag force applying the Navier-Stokes equation: $F = 6\pi r\eta v$, where F is the frictional force, r is the radius of the spherical object, η is the fluid viscosity, v is the particle's velocity. With a simpler method: $\eta = k(\rho_1 - \rho_2)t$, where k is constant, ρ_1 is the density of the particles, ρ_2 is the density of the fluid, t is the duration of ball falling (Rosencranz 2006; Hardeman 2007; Baskurt 2009).

Methods for Testing red Blood Cell Deformability

For the determination of red blood cell deformability, several methods and various approaches are known. The best-known and still in use techniques are based on the filtration method, the micropipette aspiration technique, microchannel methods and the ektacytometry (Hardeman 2007; Baskurt 2009).

Filtration technique has been used since the 1960s: measuring the passage of blood cell suspension through a filter with a certain pore diameter/size (~200 000 pores), the cells' deformability can be concluded; due to the clogging of pores, the permeability of the filtering membrane gradually decreases. The initially used classical paper filters were replaced by polycarbonate filter membranes containing cylindrical channels (diameter: 3, 5 or 8 μm , length: 10 μm). The Reid-Dormandy type filtration method utilized the filtration of red blood cell aggregation through the filter with 5 μm in diameter. Improving the principle, Dormandy and his colleagues prepared the St. George's filtrometer. The oligopore (23–30 pores) and the single pore technique (Single Erythrocyte Rigidometer, SER) are more sophisticated methods; here mainly the time of change in conductivity between the two sides of the filter correlate with presence of red blood cells just passing through the pore, where the process is analyzed by the attached computer according to the pores transit time histogram (Cell Transit Analyzer, CTA) (Hardeman 2007; Baskurt 2009; Musielak 2009).

With the *micropipette aspiration method*, a single cell can be examined, which is wholly or partly aspirated into a glass capillary with 1–5 μm diameter. From the measurement of the negative pressure and the length of the aspirated membrane phase provides shearing elastic module, while the aspiration of the whole cell gives the deformability. It requires serious technical skills (Hardeman 2007; Baskurt 2009; Musielak 2009).

The basic principle of the *microchannel method* is that the cell suspension is flowing through one or two parallel channels, or through an artificial microchannel network, while the movement of red blood cells, the transit time, and position of the cells can be visually analyzed (Baskurt 2009; Musielak 2009; Reinhart 2015).

The *ektacytometry* is based on the diffraction analysis of laser beam (wavelength: 670 nm) reflected from red blood cells suspended in high-viscosity (preferably ~30 mPas) macromolecule solution (e.g., 70 kDa dextran or 350 kPa polyvinylpyrrolidone isotonic solution) and elongated due to the shear stress, providing the elongation index (EI) in the function of shear stress (Chien 1975; Chasis 1986; Hardeman 2007). The shear stress on the sample is generated by the motor or vacuum device, while the laser diffraction pattern is captured by a CCD camera and projected on a screen. The EI can be calculated from the analyzed picture by the software diffractrogram: $\text{EI} = (L - W) / (L + W)$, where L is the length

and W is the width of the diffractogram. Different shearing geometries are used in ektacytometer devices: plane-plane rotational system in the Rheodyn device, Couette-system in laser-assisted optical rotational cell analyzer (LORCA), or vacuum-driven slit-flow technique in the Rheoscan device (Hardeman 2007; Baskurt 2009; Musielak 2009). Besides the classical deformability measurements, some modern ektacytometers are capable of testing osmotic gradient deformability (i.e., deformability test at constant shear stress over an osmotic gradient range) and membrane mechanical stability (deformability test before and after a period of mechanical shearing at definitive magnitude and duration) (Hardeman 2007; Baskurt 2009).

Further deformability measurement methods are the rheoscope technique (a combination of ektacytometry and microscopy), atomic-force microscopy, the laser optical tweezers and magnetic twisting cytometry (Hardeman 2007; Musielak 2009).

Methods for Testing Red Blood Cell Aggregation

Several indirect and direct methods are known for the determination of red blood cell aggregation. The classical and modern methods (Westergren, Seditainer, Automatic ESR) based on the already mentioned measurement of erythrocyte sedimentation rate (ESR) are widely used and well standardized methods. Also known is the determination of zeta sedimentation rate (by centrifugation) and the determination of indirect aggregation parameters (aggregation index = $(\eta_{low} - \eta_{high}) / \eta_{high}$, where η is the blood viscosity determined at a certain low and a higher speed gradient) from the results of blood viscosity measured at low speed gradient (e.g., 1 s^{-1}). By microscopy techniques or rheoscope the morphology of aggregates can also be examined and their size and red blood cell count per aggregate can be determined. By this method, the heteroaggregates (white blood cell, platelet, red blood cell) can also be separated. Ultrasound techniques enable non-invasive *in vivo* examinations (mainly B-mode echography) of aggregation developing in a certain vascular region (Hardeman 2007; Baskurt 2009, 2012b).

In clinical and experimental hemorheological studies, the most commonly used methods are based on the principles of photometry. The presence of aggregates increases the light transmission of blood sample related to a certain wavelength, as in this case the width of plasma phase (or other suspending medium) between the particles increases. In the course of disaggregation, the cells dispersed on a larger surface decreasing the plasma phase width and so the light-transmittance. When cells start to aggregate during stasis or at low shear rate, the plasma phase width and the light-transmittance increase. Furthermore, red blood cell aggregates reflect light differently compared to the individual cells. Based on these principles, different devices are available to analyze the light transmission (e.g., Myrenne MA-1 erythrocyte aggregometer), or the reflection of light (laser) from the aggregating cells (sytlectometry, e.g., LORCA). Using these methods, both the extent and the dynamics of aggregation can be examined (Hardeman 2007; Baskurt 2009, 2012b).

Thoughts on the Link between Microcirculatory and Micro-Rheological Investigations

The examination of rheological conditions of microcirculation and their interaction cannot be simplified to the correlation of Poiseuille's law related to the rigid-walled, straight regular pipes. The large region of microcirculation is not even homogenous from rheological point of view. In addition to the vein diameter and vascular geometry, the viscosity cannot be considered constant due to axial migration of red blood cells (Fåhræus and Fåhræus-Lindqvist effect), phase separation, very diverse and changeable, unsteady distribution of tissue hematocrit (microvascular hematocrit), and the particularities of the zone of individual flow (Fåhræus 1931, 1958; Wells 1964; Lipowsky 2005; Pries 2008).

Therefore, in the isolated organs, in perfusion *ex vivo* models, the solutions ensuring the stability of vessel diameter (maximal dilatation or maximal constriction) could only show a thorough picture if we hypothesized and presumed that the viscosity is constant at every stage of the circulation. This is however, obviously not true. That is why a more detailed investigation of the role of micro-rheological parameters in the microcirculation is required (Wells 1964; Lipowsky 2005; Popel 2005).

Parallel investigations of hemodynamic, microcirculatory, hemorrheological, acid-base parameters, hematological and hemostaseological factors may provide enough information to evaluate and understand the dynamics of these changes and their interactions (Baskurt 2007; Nemeth 2014b).

MAIN MICROCIRCULATORY AND MICRO-RHEOLOGICAL FINDINGS IN VARIOUS PATHOPHYSIOLOGICAL PROCESSES

Ischemia/Reperfusion

Ischemia/reperfusion injury causes all of the microcirculatory symptoms which can develop during local or systemic circulatory disorders (Ames 1968; Menger 1992; Anaya-Prado 2002; Eltzschig 2011). It appears that the ECs are primary targets during the pathogenesis of ischemia/reperfusion-induced reactions (including inflammation). Being a major source of the xanthine oxidase-derived radicals (Granger 1981; Granger 1986; McCord 1985), a microvascular dysfunction (increased capillary permeability) develops. The xanthine oxidase-derived radicals further attract neutrophils (PMNs), thus augmenting tissue injury (Hernandez 1987). The endothelium-derived oxidants promote neutrophil adhesion to ECs via endothelial production of chemotactic factors (Yoshida 1992) as well as by activation of transcription factors (e.g., NF κ B), causing an increased expression of adhesion molecules on ECs (Ichikawa 1997). Bioavailability of NO (an endogenous inhibitor of PMN adhesion) is reduced via its interaction with superoxide (Grisham 1998). This is accompanied by an activation of interstitial immune cells (macrophages and mast cells) with resultant generation of inflammatory mediators causing a chemotactic gradient which facilitates neutrophil emigration into the interstitium (Kanwar 1998). Lymphocytes may also be involved in the modulation of PMN-related reactions by releasing soluble factors, such as TNF- α or INF- γ (Osman 2009).

Micro-rheological parameters can be altered during ischemia and reperfusion by several pathways (Baskurt 2007). Impaired red blood cell deformability may contribute to an increased blood viscosity and cause perfusion problems in the capillaries (Wells 1964; Maeda 1996; Lipowsky 2005; Popel 2005). The enhanced red blood cell aggregation elevates blood viscosity and increases the flow resistance in the microcirculation (Baskurt 2007; Baskurt 2008). When erythrocyte aggregation is enhanced, the axial migration of the red blood cells in the vessel becomes more expressed, resulting in a widening cell-poor zone at the vicinity of the endothelium (Poiseuille-zone) (Fahraeus 1958). Widening Poiseuille-zone facilitates leukocyte tethering and margination; furthermore, the wide cell-poor zone slows down the rolling (Nash 2008; Yalcin 2011) (Figure 1). Additionally, altered blood rheology has an impact on the shear stress profile on the endothelial surface, thus modulating numerous vascular functions (Gori 2007, 2011; Pober 2008; Chandran 2012).

During ischemia, the local metabolic changes such as decrease in pH, increase of H^+ and lactate, affects blood cells (Weed 1969; Johnson 1985; Reinhart 2002). The pH of stagnant blood decreases in the area excluded from the circulation during the ischemia, which turns the red blood cells' discocyte shape into a stomocyte or sphero-stomocyte form (Reinhart 1980). The echinocyte and sphero-echinocyte forms may appear when the ATP depletion and calcium accumulation are dominant (Reinhart 1980). Both morphological transformations result in worsened micro-rheological characteristics: impairment of red blood cells' deformability and disturbed aggregation (Meiselman 1981; Mohandas 2008).

During stasis, hematocrit increases locally and the altered fluid distribution results in elevated protein concentration, leading to increased plasma viscosity. These factors together with the less deformable erythrocytes and aggregates formation result in an increased local blood viscosity (Koppensteiner 1996; Baskurt 2007; Nemeth 2014a). Furthermore, the mechanical trauma to red blood cells has to be taken into consideration (Kameneva 2007). The hypoxia leads to impaired EC barrier function (Gori 2007, 2011). By revascularization, the metabolites flushing into the systemic circulation together with the damaged erythrocytes may cause further changes in the microcirculation and even in remote organs (Anaya-Prado 2002; Eltzschig 2011; Nemeth 2015b).

During reperfusion, the nascent oxygen-centered free radicals initiate harmful chain reactions in the erythrocytes: damaging the cell membrane (lipid peroxidation), the transmembrane and structural proteins (receptors, ion pumps) by sulfhydryl cross-links and transforming the hemoglobin molecules (methemoglobin, Heinz-body formation) (McCord 1985; Baskurt 1997, 2007). Red blood cells are rich in iron, which catalyzes the free radical reactions through the Fenton-reaction; making these cells highly sensitive to oxidative stress (Baskurt 1997; Kayar 2001). The "second" assault of free-radicals happens by the activated PMNs during the inflammatory process that is triggered by an ischemic injury of the tissues.

NO plays an important role in the local flow regulation over the complex hemodynamic changes during ischemia-reperfusion (Anaya-Prado 2002; Eltzschig 2011). The NO has a beneficial effect on red blood cells, improving their deformability, and erythrocytes also act as an enzymatic source of NO (Bor-Kucukatay 2003; Baskurt 2007). However, in the presence of NO and $\bullet O_2^-$, peroxynitrite anion formation can jeopardize the red blood cells (Baskurt 2007).

The macro-hemorheological changes are also non-specific and are related to the acute phase reactions: increase of plasma viscosity by elevated fibrinogen concentration and α_2 -macroglobulin, increase in immunoglobulin levels, decrease in albumin level, rise in

leukocyte count, increase or decrease of platelet count, as well as hemoconcentration and erythrocytes' micro-rheological changes (Koppensteiner 1996; Baskurt 2007; Nemeth 2014a).

In the microcirculatory bed, the “no-reflow” phenomenon is characteristic for tissue ischemia-reperfusion. Despite of restarting the circulation in large-caliber vessels, there is a significant slow-down or total arrest in the microcirculatory flow (Ames 1968). In the background of this paradoxical phenomenon, numerous factors can be listed: microvascular spasm, swelling of ECs, bleb formation on the endothelial surface, increased capillary permeability, interstitial edema, micro-thrombi, neutrophil adhesion and plugging, and local acidosis (Menger 1992; Reffellmann 2002; Granger 2010; Vollmar 2011). The presence of red blood cells with impaired deformability and enhanced aggregation contributes further to the microcirculatory disturbance (Pries 2003, 2008; Lipowsky 2005; Popel 2005).

Systemic Circulatory Disorders

Hypovolemia-induced microcirculatory (arteriolar) vasoconstriction develops on the basis of an increased sympathetic activation causing A1 vasoconstriction and inverse A4 vasodilation with resultant reduction of capillary cross-sectional area and endothelial swelling (Mazzoni 1992; Szopinski 2011). Furthermore, an arteriolar hypo-responsiveness develops via up-regulation of inducible NO synthase and endothelin-1 (Liu 2005; van Meurs 2008). Widening gap junctions of the capillary endothelium is typical reaction seen also at sepsis causing tissue infiltration of PMNs (Czabanka 2007), which creates a positive feedback loop of microcirculatory derangement and obstruction of the capillary lumen (Ivanov 2006). Furthermore, red blood cell deformability is diminished (Baskurt 1998; Baskurt 2007). As a result, FCD is reduced and the oxygen delivery and removal of waste products are impaired. Similar reactions are seen in cardiogenic shock (Mazzoni 1992; Moore 2015).

Sepsis

The pathophysiology of sepsis includes several points which link it to the rheology of blood, since it is a disorder of the microcirculation (Levy 2003; Spronk 2004; Ince 2005; Trzeciak 2007, 2008; Lundy 2009; Nduka 2011; Hernandez 2013). The microcirculatory deterioration in sepsis is multifactorial. Septic process affects the entire microcirculation, disturbing micro-vascular blood flow and vascular resistance. The amount of blood entering the capillaries is affected by hemodynamic changes, redistribution of organ flow, vasodilatation and vasoplegia, as well as by opening arterio-venous shunts. Rigid blood cells may easily plug the capillaries. As result of dysfunction of the huge endothelial surface along the microcirculation, the perfusion further decreases due to increased adhesiveness for platelets, leukocytes and even erythrocytes. Microvascular thrombosis (as part of DIC) increased capillary permeability, edema and enhanced red blood cell aggregation also contributes to perfusion problems (Spronk 2004; Ince 2005; Moutzouri 2007; Trzeciak 2007; Lundy 2009; Ostergaard 2015). In a developed manifest sepsis, fibrinogen concentration increases (Baskurt 1997; Baskurt 2007; Reggiori 2009). However, in early stage, due to the fibrinogen consumption and other direct effects on blood cells, a decrease in erythrocyte aggregation might be also observed (Nemeth 2015a). Since several endothelial functions are

controlled by the shear stress via mechanotransducers, any changes in the rheology of circulating blood, and consequently in shear forces and flow profile on the vascular wall, may influence the endothelial functions (Gori 2007; Chiu 2011; Chandran 2012). Altered rheology can cause further progression in the pathophysiological process that may result in rheological changes again, as a part of a vicious circle (Baskurt 2007).

EXPERIMENTAL SURGICAL CONSIDERATIONS INVESTIGATING MICROCIRCULATION AND MICRO-RHEOLOGY

Most of the surgical investigations, by their nature, involve animal models. Using the well-defined, animal protection and laboratory animal science considerations (van Zutphen 2001), correctly designed animal experimentation is still important nowadays. Several questions exist that cannot be examined by *in vitro* methods or in tissue cultures: sufficient information can only be obtained by complex investigation in organ systems or in organs *in vivo*. Extrapolatability of the questions, i.e., their extrapolation to the original clinical issue in human references, is a further determining factor.

In view of factors determining the blood and plasma viscosity, red blood cell deformability and aggregation, and microcirculation, it is clear, that with respect to laboratory animal species, we have to expect significant interspecies and gender differences (Usami 1969; Chien 1971; Chen 1994; Popel 1994; Windberger 2003, 2007; Szabo 2006; Nemeth 2010). We have to carefully consider all these aspects when deciding on the necessity of adaptation and methodological standardization of measuring methods.

For humans the currently known hemorheological measuring methods or a measurement technique guideline is available (Baskurt 2009). This guideline covers the sampling and sample handling instructions and recommendations beside the special measurement technique details. With respect to animal experimentation, no such guideline is available; therefore, in addition to exploring the interspecies and gender hemorheological differences, we have to examine the handling and preparation details of blood samples required during the experiments, where considerable interspecies differences can also be anticipated. They can seriously influence the results, their evaluation, assessment and extrapolatability.

Another question is the way and location of blood sampling. In addition to the animal welfare considerations, such as the quantity of blood sample and the repeatability (van Zutphen 2001), we have to consider the possible arterio-venous micro-rheological differences (Nemeth 2014b).

In the detectability of the alterations, the different sensitivity and specifications of hemorheological measuring instruments and devices, such as cell size/pore size ratio during filtrometry or the orientation of cells and the viscosity of suspending medium in the ektacytometry examinations of EI need to be considered (Hardeman 2007; Baskurt 2009; Nemeth 2014a). A detailed analysis of these issues, the standardization and comparative hemorheological tests may contribute to the safe planning, performing of the experimental surgical models and to the evaluability of the obtained results with objective data.

In microcirculatory and micro-rheological investigations of animal experiments, several issues have to be taken into consideration (Nemeth 2014a):

- *Concerns a priori*: planning of experiments and techniques; counting on inter-species and gender differences (additionally: the estrus cycle of animals); careful planning of blood sampling and handling (site of sampling, required blood sample volume versus available sample volume, anticoagulant, storage); sample preparation protocols (centrifugation, buffers, etc.); standardized measurement conditions depending on the method/device.
- *Concerns a posteriori*: extrapolation, reliability.

All of these issues are important for critical revision and correct evaluation of the results, so they could be comparable and may provide useful information for the clinical medicine.

CONCLUSION

Adequate microcirculation and restored micro-rheology strikingly influence tissue oxygenation and overall tissue survival during experimental and clinical surgical interventions. Dynamic assessment of the microcirculatory functions can be conducted by numerous methods. The required spatial resolution and tissue depth as well as the type of tissue/organ of interest critically necessitate the use of appropriate microcirculatory methodology when visualization is concerned. Vascular and circulatory (cellular and micro-rheological) elements of the microcirculation have dynamic interactions and these usually show parallel changes in different surgical models. By using appropriate and up-to-date methodology, these changes can be dynamically assessed and the effect of alleviating therapies be accurately judged by using proper quantification. These findings provide a rational basis for tailoring future life-saving interventions.

Chapter 199

EXPERIMENTAL GENE THERAPY USING NAKED DNA

Eiji Kobayashi*, MD, PhD

Department of Organ Fabrication, Keio University School of Medicine, Tokyo, Japan

ABSTRACT

Experimental surgery using animal models is indispensable for applying new science developments to human clinical surgery. In recent years, attempts have been made to apply gene transfer technology in the surgical field as well as various naked genes.

In this chapter, we first introduced non-viral *in vivo* gene transfer techniques that we have applied thus far. In addition to describing the historical background of the development of the gene gun, we showed cancer treatment research and organ transplant research models implemented in small animals. We also introduced the hydrodynamic approach, which involves using catheter techniques via the arteries and veins of the target organ. We used a rat model to demonstrate that gene transfer can be effectively performed on the liver and muscles due to the characteristics of this organ and tissue. This approach was then extended to pig models. Finally, we introduced DNA vaccine in pigs via electroporation, which is a technique that is already clinically used in the veterinary field.

These advanced surgical technologies and models are expected to contribute to future research.

Keywords: gene therapy, naked DNA, pig, gene gun, hydrodynamic method, DNA vaccine

ABBREVIATIONS

AAV	Adeno-Associated Vector
ALT	Auxiliary Liver Transplantation
APC	Antigen presenting cell
CAT	Chloramphenicol acetyltransferase
CTLA4Ig	Cytotoxic T-Lymphocyte Antigen 4-Immunoglobulin

GFP	Green fluorescent protein
HBs	Hepatitis B virus surface
IVIS	In Vivo Imaging System
LacZ	beta-galactosidase
OLT	Orthotopic Liver Transplantation
Tg	transgenic

GENE GUN TECHNOLOGY IN LIVING ANIMALS

The gene gun was developed as a device to physically deliver genes to the target cell by accelerating the delivery of small particles coated with DNA using blasts from gunpowder or high-pressure gas (Figure 1). The process should be of value for studying transient and stable gene expression within intact cells and tissues (Klein 1988).

Figure 1. Theoretical schema of high-velocity microprojectiles for delivering nucleic acids into living cells. Small gold particles coated with naked DNA were accelerated by blast wind of gunpowder or high-pressure gas. Transient expression of external genes was observed in the living cells of animals and plants.

The historical background of this technological development has been summarized previously (Belyantseva 2016). A process was developed for delivering foreign genes into maize cells that did not require the removal of cell walls and was capable of delivering DNA into embryogenic and nonembryogenic tissues. A plasmid harboring a chloramphenicol

acetyltransferase (CAT) gene was adsorbed into the surface of microscopic tungsten particles (microprojectiles). These microprojectiles were then accelerated to velocities sufficient for penetrating the cell walls and membranes of maize cells in a suspension culture. High levels of CAT activity were consistently observed after the bombardment of cell cultures into the cultivars of black Mexican sweet corn, and these levels were comparable to the CAT levels observed after the electroporation of protoplasts. Measurable increases in CAT levels were also observed in two embryogenic cell lines after bombardment. Because this process circumvents the difficulties associated with regenerating whole plants from protoplasts, the particle bombardment process provides significant advantages over existing DNA delivery methods for the production of transgenic maize plants.

In the 1990s, modifications were made to substitute gunpowder with high-pressure helium gas for injection and to allow its delivery while holding the gene gun in the hand instead of within a chamber. The gene gun is now commercialized and is commonly used in experiments. The following is also a summary of the Helios® Gene Gun, which is a representative gene gun (Belyantseva 2016). The mechanical energy of compressed helium gas is used for the biolistic delivery of exogenous DNA, mRNA, or siRNA to bombard tissue with micron- or submicron-sized DNA- or RNA-coated gold particles, which can penetrate and transfect cells *in vitro* or *in vivo*. Helios Gene Gun-mediated transfection has several advantages: (1) It is simple and can be learned in a short time; (2) it is designed to overcome cell barriers, even those as tough as the plant cell membrane or stratum corneum in the epidermis; (3) it can transfect cells deep inside a tissue such as specific neurons within a brain slice; (4) it can deliver practically of any size of mRNA, siRNA, or DNA; and (5) it works well with various cell types, including non-dividing, terminally differentiated cells that are difficult to transfect such as neurons or mammalian inner ear sensory hair cells, which is particularly important for inner ear research.

We have made attempts at *in vivo* gene transfer (Yoshida 1997). For the first time anywhere in the world, we attempted to introduce marker genes *in vivo* into the liver of a rat that was directly exposed under general anesthesia. DNA-coated Au particles were accelerated by pressurized He gas to supersonic velocities to introduce a gene into the cells. Experimental and theoretical analyses both revealed a heterogeneous distribution of the particles in each shot ($1 \text{ mg Au} = 2.4 \times 10^7$ particles with $2 \text{ }\mu\text{g [32P] DNA} = 2.5 \times 10^{11}$ moles). To introduce genes into the liver of living rats, the best results were obtained with a newly developed handheld gene delivery system. The beta-galactosidase gene was introduced into the rat liver with Au particles using He at 250 psi and was expressed (1.2 $\mu\text{units}/\mu\text{g}$ protein) in a limited area of the liver surface ($8 \times 8 \text{ mm}$, depth 0.5 mm). When the same gene gun was used on a monolayer of cultured COS7 cells (about 5 μm thick), the cells in the central area of heavy bombardment were killed. Cell death caused by the influx of Ca^{2+} was prevented by the use of a cytosol-type culture medium. This method is extremely useful because genes can be easily introduced into living plants and animals without using viral vectors (Figure 2). We introduced experimental gene therapies that we have performed to date using mice, rats (Figure 3), and hamsters. Later, the possible use of this technique for the *in vivo* topical introduction of anticarcinogenic cytokines, among other genes, was examined, and the research area of this technique was expanded (Yang 1995).

Figure 2. Expression of marker genes in a plant and mouse by Helios Gene Gun. LacZ Expression (A and B) in lemon. GFP gene was applied on the surface of mouse back skin (C) and a circular fluorescent intensity was observed under excitation light (D).

Figure 3. Application of gene gun in mice and rats. Eye protector and ear plugs were prepared. Gene gun was applied on a mouse which received it with sufficient anesthesia (A). Under inhalation anesthesia, the rat liver was exposed (B).

APPLICATION FOR ORGAN TRANSPLANTATION

We have conducted experiments to determine whether this technique could be used to introduce genes into the liver. Genes can be easily introduced into the surface of the rat liver with a gene gun while also introducing the green fluorescent protein (GFP) gene as a marker gene (Figure 4). This direct introduction of DNA into liver allografts before transplantation has been considered an effective strategy for inducing protective immunity against infections and malignancies (Nakamura 2003). We examined the feasibility of the gene gun-mediated vaccination of liver grafts. Using plasmids expressing luciferase and GFP, the expression of introduced genes was tested in a graft liver. The protein expression was observed in the graft liver of hepatectomized rats and was significantly enhanced. A short course of tacrolimus

(FK506) also evoked the expression of these proteins. The effects of primary immunization of the liver on the humoral response were then tested using an expression plasmid encoding the hepatitis B virus surface (HBs) antigen and were compared to those of skin immunization alone. The results showed that local immunization of the liver strongly induced antibody formation. Furthermore, the combination of an immunized partial liver graft with tacrolimus significantly enhanced antibody production against HBs antigen. A DNA vaccine delivered to the liver is a possible strategy for preventing infectious diseases associated with liver transplantation under tacrolimus treatment.

Figure 4. *In vivo* gene transfer with a marker gene in the rat liver. LacZ gene was applied on the rat liver (A & B). Circle GFP expression was observed on the surface of the rat liver (C & D). APPLICATION FOR CANCER THERAPY

In addition, we have conducted research in the field of cancer research by expressing anticarcinogenic cytokines in the oral mucosa (Wang 2001) and muscle (Ajiki 2003). We examined the immunological effects of topical introduction into the oral mucosa by targeting the antigen presenting cell (APC) of macrophages.

Malignant melanoma in the oral cavity has a highly metastatic potential. Curative surgery is required to resect an extensive amount of oral tissue and often results in dysfunction as well as a severe cosmetic deformity in patients with the disease. An alternative technology for the local and sustained delivery of cytokines for cancer immunotherapy has been shown to induce tumor regression, suppress metastasis, and lead to the development of systemic antitumor immunity. However, local immunization of the oral cavity has not previously been studied. We examined the efficacy of particle-mediated oral gene transfer on luciferase and GFP

production (Wang 2001). The results showed that these proteins were expressed as significantly higher in the oral mucosa than in the skin, stomach, liver, and muscle. Using an established hamster oral melanoma model, particle-mediated oral gene gun therapy with interleukin (IL)-12 cDNA was then evaluated. The results indicated that the direct bombardment with mouse IL-12 cDNA suppressed tumor formation and improved the survival rate. A skin tumor model created by inoculation with melanoma cells was also significantly inhibited by the oral bombardment of IL-12 cDNA coupled with an irradiated melanoma vaccine administered to the oral mucosa compared with a treatment of a percutaneous vaccine. IL-12 gene gun therapy, combined with an oral mucosal vaccine, induced interferon-gamma mRNA expression in the host spleen for an extended period. These results suggest that immunization of the oral mucosa may induce systemic antitumor immunity more efficiently than immunization of the skin and that the oral mucosa may be one of the most suitable tissues for cancer gene therapy using particle-mediated gene transfer. To characterize the effects of the oral mucosa-mediated genetic vaccination, we also compared the antigen-specific immune responses of the oral mucosal DNA vaccine with those of flank skin vaccination against the influenza virus and the malaria parasite (Wang 2003). DNA vaccines against the influenza A/WSN/33 (H1N1) hemagglutinin and the malaria *Plasmodium berghei* circumsporozoite protein were each administered three times at 3-week intervals into the oral mucosa, skin, or liver of hamsters. The effects of the vaccines were evaluated by assessing antigen-specific antibody production and cell-mediated killing activity. Furthermore, the *in vivo* malaria challenge test was also performed after the vaccination. No significant specific antibody production was observed in any case, but interferon-gamma production and cell-mediated killing activity were strongly induced in splenic lymphocytes from hamsters given the oral vaccination. In the *in vivo* malaria experiment after the vaccination, the oral mucosal vaccination significantly delayed the blood appearance on the day that the parasites were compared with the other immunization sites ($p < 0.05$). These results suggest that gene immunization via the oral mucosa may induce cell-mediated immunity more efficiently than immunization via the skin or liver and that the oral mucosa may be one of the most suitable tissues for gene gun-based DNA vaccination against infectious diseases.

In evaluations of *in vivo* gene transfer using a gene gun, the muscle showed lasting effects (Figure 5). We then performed the following experiment. The immune response was modulated by genetic adjuvants using plasmid vectors expressing cytokines. Skeletal muscle can express a foreign gene intramuscularly administered via a needle injection, and the potential of muscle as a target tissue for somatic gene therapy in treating cancer has been explored. We investigated the efficacy of particle-mediated intramuscular transfection modified with a local anesthetic agent, bupivacaine, for luciferase and GFP expression. The results indicated that these proteins were more efficiently expressed and persisted longer in muscle modified in this way compared with the needle-injection method. Using an established rat sarcoma model, particle-mediated intramuscular gene gun therapy combined with IL-12 and IL-18 cDNA was evaluated. The growth of the distant sarcoma was significantly inhibited by particle-mediated intramuscular combination gene therapy, and the survival rate was also improved (Figure 6). Furthermore, after the combination gene gun therapy, significant levels of interferon-gamma were maintained, and a high activity level of tumor-specific cytotoxic T lymphocytes was induced. These results suggest that the sustained local delivery of IL-12 and IL-18 cDNA using intramuscular gene gun therapy modified with

bupivacaine can induce long-term antitumor immunity and has the great advantage of inhibiting the disseminated tumor (Ajiki 2003). However, it became evident that this method is not quite as effective as a long-term immunosuppressive therapy, as the expression of the genes is temporary and its effects are not expected to last for a long period of time (Ajiki, Transplantation 2003).

Figure 5. GFP expression in the regenerative muscle fibers in rats. Efficacy of gene transfection by a gene gun is independent of the cell cycle, but acts more effectively in BrdU positive myofibers.

Figure 6. Long-term GFP gene expression in the rat muscle treated by a gene gun. Experiments have recently been conducted to introduce genes into the muscle using this technique (Tsai 2016). Tsai et al. investigated the possible underlying mechanisms associated with myostatin propeptide gene delivery via a gene gun in a rat denervation muscle atrophy model and evaluated the gene expression patterns. In a rat botulinum toxin-induced nerve denervation muscle atrophy model, we evaluated the effects of wild-type (MSPP) and mutant-type (MSPPD75A) myostatin propeptide gene delivery and observed changes in gene activation associated with the neuromuscular junction, muscle, and nerve. Muscle mass and muscle fiber size were moderately increased in myostatin propeptide-treated muscles ($p < 0.05$). Moreover, the enhanced gene expression of muscle regulatory factors, neurite outgrowth factors (IGF-1, GAP43), and acetylcholine receptors was observed. Their results demonstrated that myostatin propeptide gene delivery, especially the mutant-type of MSPPD75A, attenuates muscle atrophy through myogenic regulatory factors and acetylcholine receptor regulation. Their data showed that myostatin propeptide gene therapy might be a promising treatment for nerve denervation-induced muscle atrophy.

HYDRODYNAMIC APPROACH FROM RATS TO PIGS

The hydrodynamic approach was developed as a method for injecting DNA with a large amount of solvent via blood vessels (Figure 7). This technique is similar to the aforementioned gene gun method in that it enables *in vivo* gene transfer without using viral vectors. Liu et al. described this technique as follows (Liu 2001). The need for a safe and efficient method for gene delivery has stimulated the recent emergence of vectorless methods (e.g., naked DNA) as promising alternatives to the available viral- and non-viral-based systems. Among these methods, hydrodynamic-based gene delivery through the systemic injection of DNA offers a convenient, efficient, and powerful means for high-level gene expression in mice. This new gene delivery method, as well as the potential mechanism underlying the hydrodynamic-based DNA transfer into cells, has potential applications for gene function analysis, protein expression, and gene therapy in whole animals.

We have conducted studies focusing on the superior characteristics of the liver and muscles as target organs and tissues for gene expression (Sato 2003). We applied a non-viral gene transfer method using the rapid injection of naked DNA into the graft limb in rats. Naked DNA (beta-galactosidase-, luciferase-, or GFP-expressing plasmid) was used to test an intravascular gene transfer approach under various conditions on the Lewis rat limb. Then, in a rat limb transplantation model, these marker genes were administered preoperatively (Day 2) or perioperatively (Day 0) to the graft limb using the authors' "venous protocol." The expression level of luciferase was observed over a long period using a noninvasive living image acquisition IVIS system. The effective intravascular delivery of a gene to the rat limb was achieved using a rapid bolus injection of naked DNA through the femoral caudal epigastric vein. Using this procedure, the limb graft with the marker gene perioperatively in place was safely transplanted. After limb transplantation, sustained marker gene expression was observed for more than 2 months. This was the first report showing that the method of the rapid injection of naked DNA into a limb can be applied to gene modification for organ transplantation.

Figure 7. Theoretical schema of a hydrodynamic method by use of naked DNA. A large volume of saline with naked DNA was injected through either an artery or vein in rats.

APPLICATION OF A CATHETER-BASED TECHNIQUE IN RAT MODELS

We examined a non-viral gene transfer method using the rapid injection of naked DNA targeting the liver and applied it in a rat model of liver transplantation (Inoue 2004). Inbred Dark Agouti and Lewis rats were used. To test the efficacy and adverse effects of systemic or local (catheter-based) injection, different volumes of phosphate-buffered saline containing naked DNA encoding beta-galactosidase (LacZ) were injected. Luciferase expression was followed over time with non-invasive imaging, and the cytotoxic T-lymphocyte antigen 4-immunoglobulin (CTLA4Ig) protein was tested functionally via allogenic heart transplantation. Gene transfer was then tested in rat auxiliary liver transplantation (ALT) and orthotopic liver transplantation (OLT). The timing of gene transfer was evaluated in the ALT model, and OLT was performed using a liver graft to which luciferase or the CTLA4Ig gene was transferred two days before. LacZ was expressed extensively in a volume-dependent manner; however, a large volume often induced recipient death. After the local delivery of CTLA4Ig cDNA to the liver, the survival time of Dark Agouti heart grafts increased with increases in CTLA4Ig serum levels. Liver grafts injected with naked DNA at the time of donation did not survive, but livers grafted two days after gene transfer survived. Successful expression of luciferase and production of CTLA4Ig were finally confirmed in the rat that underwent OLT. We successfully applied a non-viral hydrodynamic gene transfer method to the rat liver and showed its potential in liver grafting. The high incidence of graft failure when this procedure is performed on the day of organ donation is a potential limitation that needs to be overcome prior to clinical application.

We introduced a non-viral method of gene transfer to donor grafts using an organ-selective injection technique to up-regulate gene expression. Based on the attractive methodology of RNA interference for silencing the expression of a particular gene, we also applied our catheter-based injection method to transfer small interference RNA (siRNA)-GFP into the liver and limb grafts (Figures 8 and 9) (Sato 2005). We quantified the interfering activity after the systemic delivery of siRNA into the liver of Alb-DsRed2 transgenic (Tg) rats using an *in vivo* bioimaging system. Then, using GFP Tg Lewis rats as donors, the preoperative rapid injection of siRNA resulted in the transient down regulation of GFP expression in both the liver and limb transplantation models. Genetic modification by siRNA may provide new therapeutic options for the down regulation of endogenous antigenicity.

APPLICATION IN LARGE ANIMAL MODELS

For the first time worldwide, we successfully performed gene transference with a pig liver as the target using this technique (Yoshino 2006). We attempted to transfect naked plasmid DNA into the porcine liver using a modified hydrodynamic method. We transferred plasmid DNA to a part of the liver using an angio-catheter to reduce damage to the liver. To discern the injection conditions, naked plasmid DNA encoding GFP was transferred for use as a marker gene. The GFP gene was markedly expressed in the gene-transferred pig livers (Figure 10). In large animals, in addition to the naked gene quantity, the solution volume containing the plasmid DNA, and the injection speed, the additional treatments for the portal vein and the preparation of the hepatic artery are crucial. We found that the following injection conditions were needed: 3 mg of plasmid DNA, a solution volume of 150 ml, and an injection speed of 5 ml/s. The portal vein and the hepatic artery were clamped during gene delivery, and the blood flow of the portal vein was flushed out using normal saline. The CTLA4-Ig gene was used to test for the secretory protein. The CTLA4-Ig gene was injected with a large volume of solution via the hepatic vein specifically into the left outer lobe of the liver. CTLA4-Ig was detected in the blood of the pigs at a maximum serum level of 161.7 ng/ml 1 day after gene transfer, and CTLA4-Ig was detected for several weeks. This new technique of inserting a catheter into only a selected portion of the liver reduces liver toxicity and increased gene transfer efficiency.

With this method, gene transfer efficiency is increased by washing out the blood in the liver using a balloon catheter. This catheter technique was also applied to monkeys using AAV vector therapy (Mimuro 2013). This method results in high transfer efficiency in the liver, and studies using rats (Kobayashi 2016) and pigs (Sendra 2016) are currently underway to develop the technique for use in clinical practice.

DNA VACCINATION BY ELECTROPORATION IN PIGS

The development of a safe DNA vaccination strategy is underway following advances concerning the *in vivo* electroporation technique (Liu 2011). Advances have been made in research using pigs in particular for preclinical application (Ramanathan 2009, Luo 2016). We also evaluated universal influenza vaccines on pigs using the electroporation technique

(Figure 11). A conduction needle was inserted into the medial thigh area of a pig under general anesthesia, and the naked target DNA was injected into the central region. Gene transfer was completed by immediate conduction.

This technique has already been used in clinical practice and has been tested on hepatitis B (Yang 2017) and HIV (Huang 2017), and its effects are being revealed.

CONCLUSION

We have described the gene gun, catheter-based hydrodynamic approaches, and the electroporation technique as experimental *in vivo* gene transfer methods that do not use viral vectors while also presenting the data from our experiments via a historical background.

Chapter 200

ROBOTIC SURGERY IN EXPERIMENTAL MEDICINE

***Sandra S. Y. Kim, David Ian Harriman, MD
and Christopher Nguan*, MD***

Department of Urologic Sciences
University of British Columbia, Vancouver, British Columbia

ABSTRACT

Robotic assisted surgery has become a vitally important surgical modality developed through experimentation, innovation and collaboration between engineers, scientists, and surgeons. Digitalization of the surgeon-patient interaction allows for previously unheard of feats of engineering in procedural medicine including increased degrees of freedom of dexterity beyond human capability, telesurgery across great distances, and augmented reality. Animal models for training and testing these robotic platforms have been developed along the way which have helped the field progress. There remains a lack of randomized control trials comparing robot-assisted surgery versus other surgical modalities, however preliminary studies are promising. Despite initial upfront costs, the appeal of robot-assisted surgery continues to increase and its use will continue to expand as knowledge of how best to implement the technology continues to advance.

HISTORY OF ROBOTIC SURGERY

Robotic technology was originally developed so manufacturing industries could perform precise, repetitive and potentially dangerous jobs with intent on improving quality, efficiency and safety. The progression of robotics into the operating theatre seemed pre-ordained as there are many parallels in the ongoing challenges to improve accuracy and precision of surgical techniques to optimize patient outcomes.

Minimally invasive surgery (MIS) has a long history, as Georg Kelling first developed and performed laparoscopic surgery using a Nitze cystoscope in a dog in 1901 Germany (Hatzinger 2006). Hans Christian Jacobaeus from Sweden went on to perform the first clinical laparoscopic operation and since then, MIS adoption has steadily increased with both hand-assisted and pure laparoscopic techniques having been validated and successfully incorporated into many surgical fields around the world (Hatzinger 2006). The advantages of laparoscopic surgery over open surgery are well described and include: smaller incisions, shorter postoperative hospital stays, quicker return to normal function, decreased risk of wound infection and better cosmesis (Lanfranco 2004; Kim 2002; Fuchs 2002). Drawbacks of MIS are also recognized, specifically: loss of 3D vision, reduction of tactile feedback, amplification of tremor through rigid laparoscopic instruments, range of motion limitation, and poor ergonomics that put additional stress on the operating surgeon. In fact, these issues in MIS are thought to contribute to the steep learning curve to master complex MIS procedures (Lanfranco 2004; Prasad 2001). Robotic surgical systems were envisioned to overcome the limitations of standard laparoscopy and to further bolster the penetration of MIS procedures in more complex and restrictive scenarios.

The first surgical robots used computer interfaces and an effector arm to carry out surgical procedures. In 1985, the PUMA 560 (Programmable Universal Manipulation Arm), an industrial robot, became one of the earliest robots to be used in a clinical setting for stereotactic CT-guided brain biopsy (Kwoh 1988). ROBODOC (Integrated Surgical Systems) is comprised of a preoperative planning computer workstation and a five-axis robotic arm with a high speed milling device to more precisely core out the femur for improved placement of orthopedic implants (Bargar 1998).

In the early 1990s, NASA, the US military and researchers at Stanford combined efforts to develop telepresence robotic systems (Satava 2002). The initial impetus of telepresence robotic surgery was to provide surgical care to people over great distances per a battlefield situation, or in remote locations such as in space or deep sea scenarios (Lanfranco 2004). The first robot to incorporate telepresence technology was AESOP (Automated Endoscopic System for Optimal Positioning; Computer Motion Inc.) and approved by the FDA in December 1993. The Zeus robotic system complemented the AESOP robot and further extended its capabilities, representing the first 'master-slave' system with a separate surgeon console and robotic system (Lanfranco 2004). In a master-slave configuration, a human operator manipulates control interfaces which translate those movements to instruments manipulating the patient's anatomy; no autonomous motions are made by the robot itself. Intuitive Surgical Systems developed their own telepresence robot during the late 1990s, the daVinci robotic surgical system. These rival companies eventually elected to merge together to promote the daVinci system, resulting in the discontinuation of the Zeus platform.

The daVinci surgical system has become the de facto standard in medical robotics, and is currently the dominant surgical robotic system in clinical practice. The coincidental miniaturization and evolution of stereoscopic imaging, instrumentation, hardware and software engineering combined to make surgical robotics possible. Operations that were previously thought to be impossible without resorting to traditional open methods of surgery can now often be tackled in a minimally invasive fashion with robotic assistance. Robotic surgery remains at the frontier of surgical innovation and continues to advance the limits of conventional thinking in minimally invasive surgery.

TYPES OF TELEPRESENCE ROBOTS

There has been rapid progress in surgical robotics and their applications, and robotic MIS systems are now widely available with uses ranging from endoluminal, laparoscopic, single port to natural orifice based procedures (Barbash 2010; Lanfranco 2004; Davies 2000). The development and technology of each telesurgical system is reviewed here.

AESOP: Automated Endoscopic System for Optimal Positioning

AESOP was the first telesurgical robotic device. It was originally developed from a research grant from NASA for the development of a robotic arm to be used in the US space program (Ballantye 2002). The current iteration of AESOP is voice controlled and commands a robotic endoscope holder with 7 degrees of freedom. Urologists at John Hopkins demonstrated the success of AESOP as a surgical assistant in 17 different urological procedures (Partin 1995). The success of AESOP led to further developments in surgical robots and an influx of interest from medical technology companies.

ARTEMIS: Advanced Robotics and Telem manipulator System for Minimally Invasive Surgery

ARTEMIS was developed by scientists experienced in the nuclear and industrial applications fields, at the Karlsruhe Research Centre (Rininsland 1993). ARTEMIS is a master-slave robotic system comprised of 2 robotic arms that are controlled by a surgeon through a control console and a 3-D endoscopic system (Schurr 2000). ARTEMIS also gave the surgeon six degrees of freedom with a flexible distal robotic arm, allowing for precise motion in surgery (Rininsland 1999).

Zeus Surgical System

The Zeus robot was developed in 1999 and is a comprehensive surgical robotic system in which the surgeon controls two robotic arms attached to the bed rails of the operating table. The third arm is an AESOP for visualization, which is voice controlled. The surgeon sits

upright in a cockpit-like console facing a 2-dimensional viewing system of the operating field (Maseo 2010).

daVinci Surgical System

The daVinci Surgical System consists of 3 separate parts; 1) a master console consisting of a work station, computer and 3D display system; 2) a control tower which houses the 3D video capture equipment and synchronizers; and 3) a patient side cart comprised of a motorized wheeled platform and a vertical post with four robotic arms suspended from it. The master console translates a full 7 degrees of freedom to the instruments of the patient side cart, while the high definition stereoendoscopic cameras are mixed to provide true 3D stereoscopic views of the operative field back to the surgeon console. By converting the standard “analog” interaction of the surgeon with the patient to a digital process, the system allows for adjunctive benefits to the operator: tremor filtration, motion scaling, swapping of controls and arms, control of additional robotic arms greater than the number of master controllers through hot swapping, and all the while providing a seated, ergonomic approach to surgery which promotes the efficient and effective conduct of a potentially prolonged operation. Finally, research conducted at Intuitive and academic centers worldwide can provide surgical platform “plugins” to add novel functionality to the standard robotic system.

Typically, major operations require the assistance of an additional person at the bedside, but with the latest versions of the daVinci robot, the patient side cart’s four arms are able to be controlled by two concurrent master controller units controlled by one primary surgeon and one assistant. Although telesurgery across distances is possible with the daVinci surgical system, in North America, the FDA does not allow the use of this functionality and requires the patient and surgeon always be in the same room (Maseo 2010).

The daVinci system has evolved over time where in 1999, the original daVinci system (“Standard”) had a 2-dimensional viewing screen and 3 robotic arms, a 4th arm was added in 2003. In 2006, the daVinci S was released that had 3-dimensional high definition vision. In 2009, the daVinci Si was produced with a dual console option to aid with operative teaching and assistance, the Firefly Fluorescence Imaging System to aid in real-time visualization of tissue perfusion, the option for single site surgery, system integration with complex imaging modalities and advanced instrumentation for finer tasks. The most recent model was produced in 2014 and is termed the daVinci Xi. This model is the first major overhaul since 1999 and has redesigned instrument arm architecture to facilitate anatomical access from any position, increased flexibility of visualization through repositioning of the endoscope through any port, and a smaller footprint.

SPORT Surgical System

Titan Medical Incorporation based in Toronto, Ontario is currently developing the Single Port Orifice Robotic Technology (SPORT) surgical system, unveiled in early 2016, with the aim to expand the field of robotics surgery by lowering the cost barrier to allow for pervasive use in all surgical specialties. The SPORT is a single-incision surgical system with multi-articulated instruments, camera with 3D high definition view of the surgical field, ergonomic

work station, single-arm mobile patient cart, with single-use replaceable tips. This surgical system is not yet available for sale.

CURRENT ROBOTIC APPLICATIONS

Cardiac Surgery (Table 1)

MIS cardiac surgery became reality with advances in perfusion strategies, myocardial protection and access techniques (Bush 2013). Robotic cardiac valve and bypass surgery have become a mainstay of the discipline with use cases including: atrial septal defect closure on a beating heart, atrial fibrillation ablation and cardiac tumor resections (Gao 2010; Schilling 2012). Advantages of robotic assistance include improved cosmesis, shorter recovery and comparable outcomes to traditional techniques with the main disadvantage being prolonged operative times (Bush 2013).

Mitral valve surgery is the most common robotic assisted cardiac procedure performed, the first case performed in 1998 with an early prototype of the daVinci surgical system (Carpentier 1998). Within a week after the first robot-assisted mitral valve repair, Mohr et al. performed 5 more robotic mitral valve repairs as well as a coronary revascularization procedure (Mohr 1999). Between 2006 and 2009, Mihaljevic et al. compared key outcomes grouped by surgical technique for 759 patients undergoing mitral valve repair (Mihaljevic 2011). On average, the robot-assisted procedures took 42 minutes longer than complete sternotomy, 39 minutes longer than partial sternotomy, and 11 minutes longer than right mini-anterolateral thoracotomy ($p < 0.05$). The increased robot operative time was offset by decreased blood transfusion rates as well as lower rates of pleural effusion and atrial fibrillation compared to standard open or MIS methods, leading to significantly reduced hospital stay (median 4.2 days vs. 5.2, 5.8 and 5.1 days respectively; $p < 0.05$).

As briefly alluded to above, robotic assisted surgery has also been employed for total endoscopic coronary artery bypass grafting (TECAB). A multicenter, prospective study by Argenziano et al. assessed the safety and efficacy of TECAB surgery (Argenziano 2006). Of 85 patients undergoing TECAB surgery, 5 were converted to open procedures, 1 required reintervention for bleeding and 1 experienced myocardial infarction. Mean hospital length of stay was 5.1 +/- 3.4 days. Angiographic success, defined as patient anastomosis, was 91% and the authors concluded non-inferiority to traditional techniques. More recently, robotic surgical techniques in the absence of cardiac bypass have been performed with encouraging results (Bush 2013). From these studies, it has been demonstrated that the use of robot-assisted CABG can be successful in properly chosen operative candidates.

General Surgery

Contemporary results in the field of General Surgery show modest benefit of surgical robotics over traditional laparoscopic methods across a range of operations (Maseo 2010). Additionally, it has been estimated that per-procedure cost increases of up to \$1500 are incurred as a result of robot assistance (Barbash 2010). As such, adoption of robotic

laparoscopic techniques in General Surgery have been variable and limited with an eye towards gaining further evidence and ongoing cost containment.

Table 1. Compilation of procedures performed by surgical robots as reported in humans

Cardiac	Atrial fibrillation ablation Coronary artery bypass graft Cardiac septal defect repair: Atrial septal defect Coronary revascularization Intracardiac tumor resections Left lead implantation for pacemaker Lobectomy Mammary artery harvest Valve surgery: Mitral valve repair
General Surgery	Acid reflux surgery Bariatric surgery: gastric bypass, gastrectomy, fundoplication Cholecystectomy Colorectal resections: colectomy, low anterior resection, rectopexy, rectal resections Esophageal surgery Heller myotomy Hernia repair Pancreatectomy Splenectomy
Gynecology	Adnexal surgery Endometrial ablation Hysterectomy Lymphadenectomy Myomectomy Oophorectomy Sacrocolpopexy Tubal re-anastomosis
Neurosurgery	Image guided surgery: tumor resection, biopsy, endoscopic fenestration, ventriculostomy Myelomeningocele repair Pedicle screw placement under image guidance Transoral odontoidectomy
Orthopedic Surgery	Knee arthroplasty Image guided intra-articular injection Spine surgery Total hip arthroplasty: femur preparation/coring, acetabular cup placement
Otolaryngology	Marsupialization of a vallecular cyst Obstructive sleep apnea hypopnea syndrome treatment Parathyroidectomy Resection of head and neck tumors: laryngeal, oropharyngeal, hypopharyngeal, oral cavity Thyroidectomy Transoral robotic surgery
Urology	Cystectomy Nephrectomy: partial, radical, donor Dismembered Pyeloplasty Radical prostatectomy Ureteral Reconstruction Vasovasostomy

A large study out of the University of Illinois at Chicago assessed outcomes for 676 robotic cholecystectomies compared to 289 laparoscopic cholecystectomies (Gangemi 2016). Statistically significant differences were identified favoring robotic cholecystectomy with decreased minor biliary injuries ($p = 0.049$), decreased open conversion ($p < 0.001$) and reduced blood loss ($p < 0.001$). Mean hospital stay and number of biliary anomalies identified intraoperatively were comparable across groups. Overall, this study indicates benefit of robotic versus laparoscopic cholecystectomy. Robotic multi-port ($n = 4$) and single site cholecystectomy ($n = 5$) has been safely performed in a pediatric population (mean age 14) (Ahn 2015). Median console time was 47 minutes (range, 44–58) for multi-port cholecystectomy and 69 minutes (range, 66–86) for single site cholecystectomy. Eight of 9 patients were discharged home on day 0 with no complications. Both techniques were deemed safe in a pediatric population with possibly increased anesthetic time with single-site surgery for the trade-off of potential improved cosmesis and functional recovery.

Robotic colorectal surgery has also garnered increasing interest and a recent meta-analysis composed of data from 2 randomized controlled trials and 22 non-randomized controlled trials (5 prospective and 17 retrospective) representing 3318 patients (robotic $n = 1852$; laparoscopic $n = 1466$) compared outcomes for robotic assisted versus laparoscopic colorectal surgery (Zhang 2016). Length of hospital stay, conversion rates and blood loss were significantly reduced in the robotic group ($p < 0.05$) while the operation times (SMD = 0.78, 95% CI 0.54 – 1.02) and total costs (SMD = 1.23, 95% CI 1.01–1.45) trended in favor of laparoscopic surgery while not reaching statistical significance between groups. A separate study by Shiomi et al. assessed the advantages of robotic assisted surgery ($n^{\text{tot}} = 127$; $n^{\text{obese}} = 52$) compared to laparoscopic surgery ($n^{\text{tot}} = 109$; $n^{\text{obese}} = 30$) for lower rectal cancer and visceral obesity cases, defined as visceral fat area $\geq 130 \text{ cm}^2$ (Shiomi 2016). Robotic assisted surgery had lower overall complication rate (9.4% vs. 23.9%; $p = 0.007$), less blood loss ($p = 0.007$), shorter length of stay ($p < 0.01$) with comparable operative time and pathological results. Visceral obesity cases displayed decreased blood loss, length of stay and complication rate in favor of the robotic group (all $p < 0.05$). These results suggest that robotic assisted surgery may have advantages for challenging surgical locations and patient factors.

Gynecology

Multiple studies have compared the daVinci surgical system to standard laparoscopic myomectomy. These are technically challenging operations and many surgeons prefer open surgical approaches compared to MIS for this reason. Advincula et al., demonstrated that the use of surgical robots was associated with fewer intraoperative complications and decreased blood loss with a mean of 196 mL 95% CI [50, 700] compared to 365 mL 95% CI [75, 1550] ($p < 0.05$), increased operative time with a mean of 231 minutes 95% CI [199, 263] for the robot-assisted surgery compared to mean of 154 minutes 95% CI [138, 170] ($p < 0.05$), decreased mean hospital stay (1.5 days 95% CR [1, 3] compared to 3.6 days 95% CR [3, 8] ($p < 0.05$), and increased cost compared to traditional laparoscopic methods. The largest study comparing the daVinci surgical system to laparoscopic and open myomectomy approaches demonstrated the ability to resect larger masses with the robot (223g 95% CI [85.2, 391.5]) compared to laparoscopy (96.65g 95% CI [49.5, 227.3]) ($p < 0.001$). Additionally, robotic

surgical time was 181 minutes 95% CI [151, 265] compared to laparoscopy (115 minutes 95% CI [98, 200]) compared to open procedure time of 126 minutes 95% CI [95, 177] ($p < 0.010$) (Barakat 2011). Patients undergoing the open procedure had increased LOS of 3 days, 1 day for laparoscopic, compared to 1 day for robot-assisted surgery ($p < 0.001$) (Barakat 2011). The findings of these studies suggest that the use of surgical robots may benefit patients with complex, multiple myomas who would traditionally not be considered candidates for a minimally invasive approach.

Uterine cancer is one of the most common cancers in women, and surgical treatment consists of combination of a hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy (Weinberg 2011). The largest study to date comparing 377 robot-assisted surgeries to historical data of 131 patients undergoing open surgery for staging of endometrial cancer demonstrated that the conversion rate from robotic surgery to open surgery was 2.9% (Paley 2011). The robotic surgery group had a decreased blood loss of 46.9 mL compared to 197.6 mL ($p < 0.0001$) for open procedures, decreased intraoperative and postoperative complications (6.4% compared to 20.6% $p < 0.0001$), a higher lymph node count of 15.5 compared to 13.1 ($p = 0.007$) as well as a shorter LOS (1.4 days compared to 5.3 days for open procedure, ($p < 0.0001$) (Paley 2011).

The utility of the daVinci robot treating early stage cervical cancer with radical hysterectomy has been evaluated, given the complexity of performing laparoscopic radical hysterectomy. A study done by Nam et al. compared 32 cases each of robot-assisted as well as open hysterectomy with similar patient and tumor demographics. There was no significant difference between the operative time between the robotic and open procedures (218.8 +/- 78.3 minutes, 209.9 +/- 87.8 minutes respectively, $p = 0.654$), with similar number of lymph nodes sampled (20.2 +/- 9.4, 24.2 +/- 11.1 respectively, $p = 0.121$), and decreased blood loss (220.0 +/- 134.7 mL, 531.5 +/- 435.5 mL respectively, $p = 0.002$) (Nam 2010).

Ovarian cancer requires operative staging including: exploratory laparotomy with hysterectomy, adenectomy, abdominal-pelvic washing, omentectomy, pelvic and paraaortic lymphadenectomy, and peritoneal biopsies, as well as debulking of resectable metastatic tumor (Weinberg 2011). One study done by Magrina et al., compared 25 cases of daVinci-assisted robotic surgery for staging of endothelial ovarian cancer compared to 27 laparoscopic surgery and 119 open surgery cases over 3 years (Magrina 2011). Despite confounding variables in this study, the authors demonstrated that the robotic, laparoscopic and open treatment arms were associated with: mean operative times of 314.8 minutes, 253.8 minutes, and 260.7 minutes respectively ($p < 0.05$), decreased blood loss of 164.0 mL, 266.7 mL, and 1307.0 mL respectively ($p = 0.001$), and mean length of hospital stay of 4.2, 3.2, and 9.2 days respectively ($p = 0.08$) (Magrina 2011).

Currently there are no substantial randomized trials with long-term outcomes comparing robotic surgery efficacy and safety in Gynecology compared to traditional surgical approaches to definitively change pattern of practice, but studies remain ongoing and robotics in Gynecology remains an emerging field.

Neurosurgery

The field of neurosurgery has undergone monumental changes as a result of revolutions in stereotactic and minimally invasive surgery (Nathoo 2005) NOT IN LIST. MIS

Neurosurgery has directly led to improved patient outcomes and new surgical options for tumors that were previously thought to be unresectable, all the while improving safety for patients in these critical operations.

The initial types of robots helped surgeons perform basic stereotactic tasks, the first one of which was the PUMA 560 used to predetermine the trajectory of a brain biopsy procedure (Kwoh 1988). NeuroMate (Integrated Surgical Systems, 1987, Sacramento, California) was the first surgical robot to be approved by FDA comprises a system with 6 degrees of freedom that can be used for biopsy procedures, stereoencephalography, endoscopy, as well as deep brain stimulation with its ability to properly and accurately orient, position, hold, and manipulate tools in a 3D space with high precision and accuracy (Nathoo 2005; Haegelen 2010). NeuroArm, developed at the University of Calgary in 2001, is an ambidextrous robot designed to work within an MRI which allows the neurosurgeon to perform operations while leveraging real-time MRI scans throughout the procedure (Sutherland 2013). NeuroArm was used in 2008 to remove a brain tumor from a 21 year old patient, and since then has shown positive clinical results in other cranial neoplasia cases (Sutherland 2013; Pandya 2009).

Spine surgery saw the development of SpineAssist (Mazor Robotics, Caesarea, Israel), the predecessor to the Renaissance surgical system from the same company, which was FDA approved in 2011. Both of these surgical systems consist of a miniature robot securely attached to the operating table coordinated with real-time fluoroscopy to assist in accurate placement of spinal pedicle screws (Devito 2010). A retrospective study comparing the use of SpineAssist showed that 3204 of 3271 (97.9%) pedicle screws were appropriately placed on targeted positions by the robot (Devito 2010).

The daVinci surgical system has also been used in Neurosurgery for spinal schwannoma removal, transoral odontoidectomy, and intrauterine repair of myelomeningocele, with inconclusive outcome reports comparing robot-assisted to conventional open methodologies (Perez-Cruet 2012). However, daVinci is limited in this capacity due to reduced instrumentation availability and need for multiple access ports (Doulgeris 2015).

Current studies of robotics in Neurosurgery draw inconclusive results due to lack of good quality clinical trials and current evidence is comprised primarily of case reports or on *in vivo* models. However the increasing number of case reports from institutions illustrates the desire of surgeons to investigate this emerging technology in the context of Neurosurgery.

Orthopedics

Although the field of Orthopedic surgery pioneered surgical robotics, their use has not gained the widespread popularity and growth as seen in other surgical specialties. The external fixation of limbs in optimal position presents fewer challenges to accessing the operative field and providing adequate exposure compared to other surgical specialties which work with mobile viscera and soft tissues (Yen 2010).

Traditional knee replacement surgery (TKR) involves intraoperative sizing guides to assist the surgeon determine the appropriate implant size to ensure a tight fit between the bone and prosthetic. Intraoperative cutting errors and resulting gaps can lead to delays in bone growth and increased use of bone cement in such cases. Many surgical robots were developed for the purposes of knee arthroplasty, with only few of them having clinical success throughout the world. These robots include the CASPAR system (URS Ortho Rastatt,

Germany), RGA system (formerly known as ACROBOT), ROBODOC system (Curexo Technology Corporation, Fremont, California, USA), and the Robotic Arm Interactive Orthopedic System (RIO; MAKO Surgical Corporation, Fort Lauderdale, Florida, USA), with the most commonly used orthopedic surgical robots being the ACROBOT and ROBODOC systems (Netravali 2013).

The Active Constraint ROBOT (ACROBOT) was first developed in Imperial College in London, United Kingdom (Jakopec 2003) and is now known as the Stanmore Sculptor Robotic Guidance Arm (RGA) system (Stanmore Implants, Elstree, UK) (Netravali 2013). Its main parts include a high-speed cutter mounted on a robotic device that uses 3D reconstruction and visual guidance to precisely target and core out long bones for implants (Cobb 2006). The ACROBOT allows free movement inside a predetermined safe region, however, motion at the boundaries becomes progressively more stiff, preventing inadvertent errors (Jakopec 2003). A prospective double-blind randomized control trial by Cobb et al., compared conventional and robot-assisted unicompartmental knee arthroplasty in 27 patients using the ACROBOT system showed increased operating time but significantly better alignment that achieved near normal coronal plane alignment within 2 degrees of the targeted position with the ACROBOT, while only 40% (6/15) of the conventional method resulted in this degree of accuracy (Cobb 2006). Likewise, the difference between tibiofemoral angles planned and achieved favored ACROBOT assistance (0.65 ± 0.59 degrees vs -0.84 ± 2.75 degrees respectively, $p = 0.001$). Three other studies done by Coon, Pearle et al., and Plate et al., also evaluated the use of robot-assisted unicompartmental knee arthroplasty, which all demonstrated more accurate implant placement, improvements in restoration of natural knee kinematics, and positive outcomes for implant survival as a result of accurate placement of implants (Coon 2009; Pearle 2010; Plate 2013).

ROBODOC is one of the first clinically successful robots, and is the first robot to be approved by the FDA to be used in orthopedic surgery (Karthik 2015).

Robot-assisted total hip arthroplasty (THR) was originally performed with ROBODOC in 1992 and has been used in over 24,000 surgeries worldwide with data showing improved patient outcomes, with more precise implant positioning and elimination of intraoperative femoral fractures (Bargar 1998). A study done by Harris et al., compared the surgical outcomes of hip replacements performed in three different centers with 69 ROBODOC-assisted total hip replacement compared to 65 control cases. As with knee replacement surgery, the robot-assisted procedure was associated with longer operative times (258 minutes, which was later reduced to 90 minutes with surgeon experience, compared to 134 minutes for the control group, $p < 0.0001$) (Bargar 1998). Blood loss was reported to be higher in the robot-assisted group (1189 mL compared to 644 mL compared to the conventional open surgical method, $p < 0.0001$), and average length of stay was not significantly different between the two groups (8.2 days for the ROBODOC and 7.5 days vs. control) (Bargar 1998). Postoperative complications including intraoperative fractures, dislocations, partial sciatic nerve palsy, deep vein thrombosis and pulmonary embolism were evaluated with no significant differences in complication rates between the two treatment groups, other than no intraoperative femoral fractures in the ROBODOC group compared to three in the control group ($p < 0.01$) (Bargar 1998). The modified Harris hip scores postoperatively showed no difference in the first year favoring the robotic group (89.4 for the ROBODOC vs 86.6 for the control group), and two years (88.5 for the ROBODOC vs. 91.1 for the control group) (Bargar 1998).

The innovative motion (INNOMOTION, Innomedic, Herxheim & FZK Karlsruhe Germany & TH Gelsenkir, Germany) allows for robot-guided intraarticular injections into the many joint articulations of the foot under CT or MRI guidance, including: calcaneocuboid, subtalar, tarsometatarsal, talonavicular, and tibiotalar joints. INNOMOTION was successful in infiltrating all 16 joints of patients (N = 16) with no intra or postinterventional complications. Small case studies to date have shown that patients had relief of pain following injections with a preinterventional pain measurement visual analogue scale (VAS) 5.3 +/- 2.33 to a score of 1.1 +/- 1.45 postinterventionally (Wiewiorski 2009).

Surgical robotics in Orthopedic surgery has a long and storied history, and remains an active area of research and development. Given the current widespread use of mechanical instruments in the field of Orthopedic surgery, lends the specialty especially well transition into the world of robotics surgery.

Otolaryngology

The field of Otolaryngology has traditionally performed procedures involving large incisions and extensive surgical dissections to adequately perform head, neck and airway surgeries to minimize damage to vital structures (Oliveira 2012). Thus the nature of these surgical procedures can lead to significant tissue damage, extended time to functional recovery, decreased cosmesis, and decreased quality of life (Garg 2010). Robotic assisted surgery is well poised to positively affect these negative patient outcomes (Oliveira 2012).

The daVinci robot is currently used for Transoral Robotic Surgery (TORS) and was FDA approved in 2009 (Moore 2009). TORS surgery involves the use of the oral cavity as an entry site, and was first carried out by McLeod and Melder for marsupialization of a vallecular cyst in 2005 (McLeod 2005). This technique was further adapted and developed by Weinstein and O'Malley in 2006 on three human patients with tongue base cancers (O'Malley 2006).

There are few studies to date looking into the functional surgical outcomes associated with patients undergoing TORS for oncologic resection in the head and neck. Case reports of a variety of different surgical procedures performed in head and neck regions from the oropharynx, laryngopharynx, oral cavity, skull base surgery (infratemporal and parapharyngeal fossae), thyroid glands, and in pediatric airways have been documented (Garg 2010). The most comprehensive study thus far was done by Boudreaux et al. in 2009 with 36 patients with laryngeal, oropharyngeal, hypopharyngeal, and oral cavity tumors. Although 36 patients were recruited for the study, only 29 (81%) underwent successful robotic resections with negative surgical margins reported in all 29 patients (Boudreaux 2009). Of the 7 patients who failed to undergo successful robotic resection of their tumors, the biggest factor was adequate and appropriate exposure of the surgical site, extensive infiltrative tumor requiring free-flap reconstruction, or patients opting for chemotherapy or chemoradiotherapy treatments instead (Boudreaux 2009). The mean robotic operative time was 99 +/- 32.6 minutes, mean estimated blood loss was 51 +/- 42 mL and no transfusion was required for any cases (Boudreaux 2009). The mean hospital stay was 2.9 +/- 2.9 days, and 16 of the 29 patients (55%) were able to return to oral nutrition prior to discharge. Postoperative complications were limited to bleeding in 4 patients, one whom required cautery and another as a result of coumadin therapy several days postoperatively. 21 patients (21/29, 72%) undergoing TORS were safely extubated prior to exiting the operating room, and 7 patients required

postoperative intubation with only one patient requiring a planned short term tracheotomy tube placement. This study demonstrated that TORS is a safe surgical alternative for patients with suitable airway anatomy and limited tumor disease pathology, however, further studies comparing TORS to conventional open procedures will need to be carried out to further elucidate the benefits of using the daVinci robot in these procedures.

The use of TORS has also been extended to non-malignant lesions in the head and neck. Vicini et al., in 2012 assessed the utility of TORS in treating obstructive sleep apnea hypopnea syndrome in 20 patients. The mean operative time was 42.5 +/- 15.2 minutes, with a mean setup time of 31.2 +/- 18.2 minutes and estimated blood loss was at 27.7 +/- 13.6 mL (Vicini 2012). There were no serious intraoperative or postoperative complications in this study other than minor bleeding managed non-surgically in three patients (Vicini 2012). Evaluation of the surgical outcome was done through the apnea hypopnea index (AHI) score and Epworth sleepiness scale (ESS) with improvements of 24.6 +/-22.2 for AHI and 5.9 +/-4.4 for ESS, and using cutoff values of AHI, ESS, and oxygen saturation levels postoperatively, 12 (60%) of the patients were considered to be cured (Vicini 2012).

The use of the daVinci has been evaluated more extensively in the case of thyroidectomies, comparing it to the conventional open method. The first case was performed by Lobe et al., in 2005 who used a transaxillary robotic technique to resect a thyroid nodule in one patient and placement of a vagal nerve stimulator for intractable seizures in another (Lobe 2005). A recent systematic review and meta-analysis looked at 11 articles comparing robot-assisted thyroidectomy to conventional open procedures. The mean operative time for robot-assisted thyroidectomy was increased compared to conventional open methods by 48.1 minutes 95% CI [33.6, 62.7] in total thyroidectomies and by 37.3 minutes 95% CI [12, 62.5] in subtotal thyroidectomies (Sun 2014). Conversion from robot-assisted to open cases was required in 2 out of 243 cases (0.8% cases). Length of hospital stay was decreased in the robot-assisted thyroidectomy group by -0.006 days 95% CI [-0.25, 0.24]. There was no significant difference between the two patient groups in terms of postoperative complications including hematoma or seroma formation, recurrent laryngeal nerve injury, hypocalcemia, or chyle leak, (Sun 2014). Postoperatively, the conventionally open procedure treated patients had increased severity of voice symptoms at postoperative day 1 ($p = 0.008$), first month postoperatively ($p = 0.049$), 3 months postoperatively ($p = 0.043$), but not at 6 months (Tae 2012).

The feasibility of skull base surgery was first demonstrated by O'Malley and Weinstein in humans in a patient who underwent parapharyngeal cystic neoplasm resection in the infratemporal fossa with no adverse surgical events such as damage to many vital structures (carotid artery, jugular vein, cranial nerves) (Oliveira 2012). Further development of appropriate instruments for Otolaryngology in terms of size, function, and flexibility will be needed prior to execution of more robot-assisted skull base surgery in Otolaryngology patients (Oliveira 2012).

Urology

The field of Urology has been a frontrunner in exploring surgical robots use in a spectrum of operations. The first reports of the use of the daVinci robot in surgery were described by Partin et al. in 1995 who utilized robotic assistance as surgical assistant

substitutes during 17 laparoscopic procedures (Burch bladder suspension (N = 2), nephrectomy (N = 4), nephropexy (N = 1), orchiopexy (N = 1), pelvic lymph node dissection (N = 1), pyeloplasty (N = 3), retroperitoneal lymph node sampling (N = 2), varix ligation (N = 2), and ureterolysis (N = 1) (Partin 1995). The study reported no increase in total operative time when the robotic arms were used, and no difference between the set up and take down times for the robot-assisted surgeries compared to the conventional laparoscopic surgical assists ($p > 0.05$) (Partin 1995). DaVinci robot-assisted prostatectomy (DVP) is the most frequently performed robotic procedure worldwide, and has supplanted both laparoscopic and open approaches at many centers (Barbash 2010). There remains insufficient data to determine if robotic prostatectomy can decrease the long term rates of impotence and incontinence which are potential complications of this operation. However, introduction of robotic Urology has changed the landscape of radical prostatectomy operations as a whole, as it has leveled the steep learning curve of laparoscopic prostatectomy and allowed an entire population of MIS-naïve surgeons seemingly the ability to offer an MIS approach to this procedure overnight (Barbash 2010).

The literature supports the fact that DVP leads to significantly less blood loss secondary to improved visualization of the dorsal venous complex coupled with the tamponade effect of the pneumoperitoneum compared to conventional open or laparoscopic methods (Jain 2015; Skolarus 2010; Krambeck 2009).

Comparing robot-assisted radical prostatectomy to traditional open procedures, the current studies show longer operative time for robot-assisted laparoscopic prostatectomy (2.3 hours for open and 4.8 hours for robot-assisted, $p < 0.001$) in the early phases of the learning curve with decreased operative time with increased robot-assisted surgical cases (N = 200) (163 minutes for open and 160 minutes for robot-assisted) (Menon 2002; Tewari 2003). Transfusion rates were lower in the robot-assisted group compared to the open surgical treatment group with a relative ratio of 4.51 95% CI [1.35, 15.03] ($p = 0.01$) (Ficarra 2009). Only a single study by Tewari et al., looked into mean catheterization time which demonstrated a lower catheterization time in robot-assisted treatment group of 15.8 days for open compared to 7 days ($p < 0.05$) (Tewari 2003). The current studies comparing the various surgical modalities show similar rates of complication in prostatectomies in the different treatment groups, with the exception of the study done by Tewari et al., which demonstrated a 20% intraoperative complication rate for open surgical group (N = 100) compared to 5% in the robot-assisted surgical group (N = 200) ($p < 0.05$) (Tewari 2003).

Comparison of laparoscopic prostatectomy to robot-assisted prostatectomy showed similar mean operative time after 20 robot cases (Ficarra 2007). The cumulative weighted mean difference for the mean operative time were overlapping in laparoscopic compared to robot-assisted treatment groups with a faster operative time in the laparoscopic group of -19.39 minutes 95% CI [-49.34, 88.13] ($p = 0.58$) and an increased weighted mean difference blood loss in the laparoscopic group of 19.45 mL 95% CI [-112.53, 106.73] compared to robot-assisted prostatectomy (Ficarra 2009). Robot-assisted prostatectomy did not have significant differences with regards to transfusion rate, in-hospital stay, or catheterization time, with conflicting results with regards to overall complication rates (Ficarra 2009). The cumulative analysis of very limited data looking into urinary incontinence after robot-assisted or laparoscopic prostatectomy shows a similar relative risk of 0.87 95% CI [0.54, 1.39] ($p = 0.56$) for the two groups, and one study looking into recovery of erectile function demonstrated a median time to erectile function recovery of 440 days for open prostatectomy

compared to 180 days for robot-assisted prostatectomy ($p < 0.5$) and median time to intercourse of 700 days for open compared to 340 days for robot-assisted procedures ($p < 0.05$) (Ficarra 2009; Tewari 2003).

The oncologic outcomes following DVP (biochemical recurrence, positive surgical margins) appear similar between robot-assisted and conventional open radical prostatectomy (Masterson 2013; Barocas 2010). A cumulative analysis of studies found similar reports of positive surgical margins amongst robot-assisted and laparoscopic prostatectomy with a relative risk of 1.08 95% CI [0.97, 1.19] ($p = 0.17$) (Ficarra 2009). Recent systematic review and meta-analysis looking into the current studies of oncological outcomes associated with robot-assisted prostatectomy showed positive surgical margins with a mean of 15% in all cases and 9% in localized cancers (Novara 2012). Only very few studies reported follow up over 5 years with a 7 year biochemical recurrence-free survival being 80% for robot-assisted prostatectomy (Novara 2012). Cumulative analysis comparing robot-assisted prostatectomy to open prostatectomy showed similar positive surgical margins with an odds ratio of 1.25 ($p = 0.19$) and similar biochemical recurrence survival estimate hazard ratio of 0.9 ($p = 0.526$) (Novara 2012). Looking into robot-assisted prostatectomy compared to laparoscopic prostatectomy, the studies also demonstrate similar positive surgical margins with an odds ratio of 1.12 ($p = 0.47$) and similar biochemical recurrence survival estimate hazard ratio of 0.5 ($p = 0.141$) (Novara 2012).

The promising results of DVP and the demonstration of technical success of the platform in a restricted space performing complex reconstruction, paved the way for expansion of daVinci applications to other urological procedures. MIS radical nephrectomy procedures for renal cell carcinoma is a prime example of the benefits of minimally invasive surgery as there are well documented reductions in (LOS), pain, improved cosmesis and earlier return to activity. However, MIS partial nephrectomy, in which only a portion of the kidney is removed which harbors a tumor, followed by reconstruction of the remaining kidney, is a much more technically challenging operation and one for which daVinci has proven effective (Fergany 2000). The operation is often stressful as the renal hilum is clamped, depriving the kidney of blood during the resection, but also instituting a time limit to complete the procedure within 30 minutes. A retrospective review of daVinci partial nephrectomies performed at four large centers in Europe and United States by Benway et al. (N = 183), reported a mean ischemic time of 23.9 minutes (range: 10–51 minutes), a mean total operative time of 210 minutes (range: 86–370 minutes) with the robot, and a mean estimated blood loss of 131.5 mL (range: 10–900 mL), the tumor size was positively correlated with both the operative time ($p = 0.003$) and warm ischemic time ($p = 0.005$), with a mean tumor size of 2.87 cm (range: 1.0–7.9 cm). Two cases (1%) were converted to open partial nephrectomies due to failure to progress (extensive perinephric scarring in one patient and another failure to identify tumor in intraoperative ultrasounds). A total of 18 (9.8%) complications were reported in the study with 15 (8.2%) being major in nature, such as two postoperative bleeds requiring transfusion, two postoperative urine leaks (stent placement and drainage), hepatic laceration in one patient and splenic laceration in another, two chylous leaks, three pseudoaneurysms requiring embolization, one subscapsular renal hematoma, and two patients suffering from postoperative stroke and one myocardial infarction, with no fatalities. There were 3 (1.6%) minor complications such as incisional cellulitis and self-resolving gross hematuria, with no reported disease-specific mortalities. However, continued

investigation of the efficacy of daVinci partial nephrectomy is required to document long term outcomes (Wu 2014).

The current gold standard treatment for muscle invasive bladder cancer is radical cystectomy. Laparoscopic radical cystectomy leads to lower morbidity and comparable oncological outcomes compared to open radical cystectomy (Haber 2007). The familiar benefits and MIS approach including: decreased hospital stay and blood loss, and early recovery from ileus are also reported benefits of daVinci robot-assisted radical cystectomy (Nix 2010). Staging pelvic lymph node dissection during these operations can be challenging via laparoscopy, but robot approaches yield numbers similar to that of the open procedure (Hellenthal 2011). It should also be noted that currently the preference is to complete the urinary diversion step of radical cystectomy via extracorporeal technique, although methods have recently been developed to facilitate a completely intracorporeal reconstruction (Pruthi 2010). A study evaluating the learning curve for robot-assisted radical cystectomy was appraised at 14 different institutions (N = 496) (Hayn 2010). Mean operative time for daVinci cystectomy was 441 minutes, 368 minutes, and 307 minutes for surgeons who had performed <30, 30–50, or >50 cases respectively ($p < 0.0001$). The median lymph node yield increased by 73% amongst surgeons who had done <30 or >50 cases ($p < 0.0001$), with lymph node yields of 13, 18, or 20 for surgeons who had performed <30, 30–50, or >50 cases respectively ($p < 0.0001$). The mean estimated blood loss was 477 mL (N = 476), 283 mL (N = 193), and 451 mL (N = 419) with surgeons who had performed <30, 30–50, or >50 cases respectively ($p < 0.0001$). The mean length of hospital stay was found to be 12 days, 10 days, and 12 days in the groups with surgeons who had performed <30, 30–50, or >50 cases respectively ($p = 0.4889$) and 21%, 27%, and 26% of cases performed by surgeons who had performed <30, 30–50, or >50 cases respectively required transfusions ($p = 0.2923$). Positive margins were found in 12%, 10%, and 6% of cases performed by surgeons who had performed <30, 30–50, or >50 cases respectively ($p = 0.6054$).

Benefits

Surgical robotics originally had foundations in the US military's desire to deliver specialized care in forward hospitals without risking these specialized human assets' lives. Following the advent of telesurgical robotics, refinement in the platform followed parallel developments in the fields of computational power and complexity, hardware miniaturization, and videoendoscopy. While traditional open surgery allows for wide operative field visualization and manipulation and the recruitment of surgical assistants, traditional laparoscopy suddenly handcuffed the surgeon, limiting their range of motion, degrees of freedom and taking away depth perception during conduct of the operation. For these reasons, surgeons wishing to implement laparoscopy into their practice must undertake specific training in MIS techniques as there is a steep learning curve to relearn how to conduct procedures under such restrictive conditions. Surgeons were willing to continue to push MIS procedures over traditional open procedures despite the difficulties inherent in the surgical modality as there quickly became obvious benefits to patient postoperative recovery and return to normal function. At this point, surgical robotics fortuitously matured into a viable entity and quickly gained popularity as it severely flattened the learning curve to deliver MIS style surgical approaches. The robot added back increased dexterity and range of motion,

improved visualization and depth perception, motion scaling and tremor filtration, and did away with the fulcrum effect; all factors which made minimally invasive surgery distinctly foreign, now made entirely intuitive (Prajapati 2012; Lanfranco 2004; Davies 2000).

Incorporation of robotic MIS has promoted the undertaking of surgical procedures previously thought to be too technically challenging or complex using laparoscopic methods. The development of “endowrist” technology which places an additional joint next to the tip of the instrument allows for fine, dextrous movements and a full 6 degrees of freedom, further increased the impression of deploying and controlling miniaturized virtual “hands” in the operative field. To many, it was essentially inconceivable to perform complex MIS procedures on the brain or spine, or pelvis, and the field of robotics has shown that these are not only feasible, but also often with improved patient outcomes.

Limitations

Despite its accelerating popularity and traction in the health care delivery landscape, there remain some disadvantages to surgical robotics, and there are currently no definitive high quality clinical trials comparing robotics to other MIS procedures. Furthermore, compared to other surgical methods such as their laparoscopic counterparts, there are very little long-term follow-up studies on patients of robotics-assisted surgery (Lafranco 2004; Maseo 2010; Weinberg 2011; Karthik 2015).

With any new technology comes additional cost, and robotic surgery is no exception. The capital cost of acquiring the daVinci surgical system is on the order of \$3–5 million dollars (Turchetti 2012; Barbash 2010). The robotic instruments are the principal driver in incremental cost as they are disposable consumables which may be used a maximum of 10 cases before being decommissioned through an internal mechanism (Maseo 2010). A study published in the *New England Journal of Medicine* by Barbash and Sherry showed that on average across 20 different types of surgeries, the incorporation of robots into the procedure adds about \$1600, or 6% to the cost (Barbash 2010). Intuitive Surgical is the sole provider of commercially available surgical robots and enjoys a monopoly in the market to date. The prohibitive cost of implementing a robotic surgery program can prevent more widespread adoption outside of large, academic centers (Kim 2002). Contemporary surgical training programs in North America particularly in the USA often teach trainees operations via robotics approaches first, and thus this generation of surgeons and those following are destined to accept these technologies as just a part of the standard armamentarium in the delivery of patient care. Even still, it is important to recognize that like any surgical procedure, it is estimated that one would need to perform 150 to 250 procedures prior to becoming proficient, and anywhere between 8 to 150 cases to reach a plateau on the learning curve (Barbash 2010; Jain 2015).

Another limitation of surgical robots is their physical presence in the operating rooms (Lafranco 2004). These machines are large, and take up valuable operating room real estate, particularly in already crowded operating rooms with other essential equipment and personnel. Questions have been raised as to safe conduct of procedures in these cramped quarters, however, these concerns may be circumvented with future development of smaller robots, or larger operating rooms built with these technologies in mind (Savata 2001). Already, between the daVinci Standard and the most recently released version, the daVinci

Xi, there has been a significant reduction in footprint and resources required for the robotics platform in the OR.

The primary limitation in preventing widespread use of surgical robots is the prohibitive cost of purchasing and maintaining the robot, prolonged operative time which can further prolong surgical wait lists, and the need for specially trained operating staff and surgeons. It is predicted that with time, these limitations will be overcome; some through market competition, and some through “network effects” in that the more robots are in use, the more robotic operations are integrated, the more robots are purchased, and so on.

Training Models

Intuitive surgical has developed the daVinci Skills Simulator™ which consists of various modules designed to gain comfort in basic robotic skills such as endowrist manipulation, camera and clutching, fourth arm integration, system setting, needle and control driving and energy and dissection (Intuitive Surgical 2016). Cho et al. prospectively assessed if this trainer could improve performance (Cho 2013). 12 subjects were randomized into 2 groups, virtual reality plus standard training ($n = 6$) versus standard training alone ($n = 6$), to assess needle control and suturing. Participants were evaluated across two time points with the intervention group undergoing virtual reality training in between. Those subjects in the virtual reality group displayed significantly improved performance skills ($p = 0.028$) and suturing time (7.1 ± 1.54 minutes versus 10.55 ± 1.93 minutes, respectively; $P = .018$). Improved performance following robotic virtual reality simulation training has also been verified by other investigators (Foell 2013).

Robotic training on inanimate objects has gained popularity. Finan et al. created a dry lab in which the procedure for robotic hysterectomy was broken down into critical steps of the operation (i.e., identification of ureter, suturing vaginal cuff, etc.) (Finan 2010). They used objects such as balloons, rubber bands, nails, a ‘beer huggie’, foley catheters and plywood to model female anatomy. 16 residents were put through the dry lab training and graduated to live surgery if they showed proficiency at the critical steps as judged subjectively by an expert. 10 of 16 residents were granted permission to move onto live surgery performing key parts or the entire robotic hysterectomy with no complications to date.

Animal models are another mainstay of robotic surgical training. Mehrabi et al. used a small (rat) and large (porcine) animal model to evaluate performance improvement over time for visceral and vascular robotic surgical procedures (Mehrabi 2006). 4 trainees with different experience level underwent a baseline evaluation in a porcine model for cholecystectomy, gastrotomy, anastomosis of small intestine and aorta. Following this, training on a rat model performing 4 procedures each of gastrotomy and anastomosis of colon, aorta and small intestine was performed. Finally, re-evaluation on the porcine procedures occurred to conclude the study. Operative times significantly improved for everything except cholecystectomy (11 min and 8 min for cholecystectomies; $p = 0.24$, 18 and 10 min for gastrotomies; $p = 0.002$, 28 and 18 min for anastomosis of small intestine; $p = 0.007$, and 25 and 12 min for anastomosis of the aorta; $p = 0.049$). Also, complication rates and performance quality significantly improved for all procedures across time points as gauged by expert evaluators ($p < 0.05$). In the field of Urology, a novel robot-assisted partial nephrectomy model consisting of an ex vivo porcine kidney with an implanted Styrofoam ball mimicking

the tumor was developed and tested by Hung et al. (Hung 2012). This study divided participants into 3 groups based on number of robotic cases completed: expert (>100 cases; $n = 13$), intermediate (1–100 cases; $n = 9$), and novice (0 cases; $n = 24$). Partial nephrectomy using the daVinci Si was performed by each group, with each procedures being judged by 3 blinded expert reviewers using the validated Global Operative Assessment of Laparoscopic Skills tool (Vassiliou 2005). Expert surgeons outperformed the other groups in all performance metrics ($p < 0.05$) and felt the model may be beneficial for residents and fellows, but they were unsure how useful it would be for more experienced surgeons.

Hung et al. designed a study to gauge the relative performance of three standardized robotic training methods: virtual reality using the da Vinci Skills Simulator™, structured inanimate tasks and a live porcine model (Hung 2013). Two groups were identified consisting of urology residents (novice) with median (range) of 0 (0–20) robotic cases ($n = 38$) and faculty surgeons (expert) with median (range) of 300 (30–2000) robotic cases ($n = 11$). Blinded experts graded performance using the Global Evaluative Assessment of Robotic Skills tool (Goh 2012). As expected, experts received higher scores than novices over all three training methods ($p < 0.001$). Performance on all three methods was found to be strongly correlated ($p < 0.001$) indicating cross method validity, thus signifying the training value of each of these training methods.

Telesurgery

The master-slave configuration of the daVinci robotic surgical system has the primary surgeon sitting at a console that is connected to robotic effector arms via a series of cables. A logical extension of this set up is to increase the distance between the console and the robot to allow greater access to expert robotic surgical therapy. Telesurgery over great distances has the potential to deliver quality surgical care to people of remote areas without the added costs of travel and logistics. Additional benefits are quite intuitive, as clearly identified by two of the original collaborators of the technology; NASA and the USA army. Both of these groups hope to be able to deliver surgical care to their personnel either in space or on the battlefield (Satava 2002). Additional advantages include surgeon safety, as there are reports of surgeon morbidity when travel is required (Cazac 2014), and telementoring whereby novice surgeons can receive active feedback from expert surgeons across the world (Ballantyne 2002).

Pre-surgical telesurgery trials have been performed with encouraging results. Ngan et al. used an Internet-based virtual private network (VPN) with data transfer speeds of 17 Mb/s to assess robot-assisted laparoscopic pyeloplasty in a porcine model over a distance of 2848 km with the daVinci system (Ngan 2008). Surgical anastomotic times for the 6 porcine pyeloplasties were evaluated. Despite connection latency of 370 ms, the procedure was feasible with average anastomosis of 20.7 +/- 4.7 min. In a separate study, Ngan et al. performed 18 total robotic-assisted pyeloplasties with the Zeus system on a porcine model using real-time ($n = 6$), Internet-based VPN ($n = 6$) and satellite network connections ($n = 6$) (Ngan 2008). Latency and operative time did not reach statistical significance between groups and were as follows: real time (0 ms; 41.3 +/- 15.0 min), VPN (66.3 ms; 47.0 +/- 24.1 min) and satellite (560.7 ms; 51.8 +/- 4.7 min). Both the landline and satellite groups had 2 of 6 anastomoses display mild leak with pressure test of 100 cmH₂O whereas the real time procedures had no such leak. Finally, despite no statistically significant results between

groups, surgeons subjectively reported that pyeloplasty was more difficult with delays between actions and response in the landline and satellite groups.

Innovative communication systems are necessary to achieve more widespread accessibility to telesurgery while also minimizing latency of data transfer. Sterbis et al. have shown that telesurgery is feasible over public Internet (Sterbis 2008). Using a combination of telementoring and telesurgical approaches, 4 robotic assisted porcine nephrectomies were carried out with the primary surgeon greater than 1200 miles away. Data transfer delays were between 450 to 900 ms, however blood loss was minimal, there were no inter-operative complications and all surgeries were successfully performed. A group from the University of Washington, in collaboration with the US military is attempting to develop a fully mobile, wireless robotic telesurgery system (Lum 2007). This group implemented a study in which a surgical robot was deployed in the Simi Valley desert of California for experiments on an inanimate model with communication facilitated via an Unmanned Aerial Vehicle in the HAPs/MRT (High Altitude Platform/Mobile Robotic Telesurgery) project. Time delay between console and robot was 200 ms for video stream and 20 ms for robotic control signals with no loss of signal. This communication system, along with the development of deployable surgical robot systems such as “The Trauma Pod” with the purpose of being a rapidly deployable robotic system with no human personnel that can be telesurgically controlled to perform critical life-saving procedures on wounded soldiers on the battlefield, could be used to perform complex care to people in disaster areas, on the battlefield or in other remote areas (Garcia 2009).

In 2001, a surgeon in New York performed the first long distance telesurgical operation by performing a laparoscopic cholecystectomy on a patient in Strasbourg, France over 14000 km away (Marescaux 2001). This was accomplished with the Zeus robotic system and a dedicated fiber optic line, known as Asynchronous Transfer Mode (ATM), with a rate of data transfer of 10 Mb/s. The 68 year old patient who was operated on recovered well from the surgery without complication. In Canada, telesurgery has been practiced between McMaster University in Hamilton, Ontario and North Bay, Ontario located 400 km apart, also with the Zeus robotic system (Anvari 2005). Between 2003 and 2005, Dr. Anvari and colleagues were able to perform 21 robot-assisted laparoscopic telesurgeries using an internet protocol virtual private network with 15 Mb/s of bandwidth which included 13 funduplications, 3 sigmoid resections, 2 right hemicolectomies, 2 inguinal hernia repairs and 1 anterior resection. Latency experienced by the telerobotic surgeon was 135–140 ms. Surgeries were performed in a comparable time to on-site laparoscopic surgery with no significant surgical complications or increases in post-operative stay.

Despite the excitement, there are several concerns regarding telesurgery that has limited widespread acceptance. First, remote locations that may benefit from telesurgery may not currently have skilled individuals to set up the robot platform required for surgery or take control of the operation should a complication arise. Second, hospital and communication infrastructure in non-urban centers may be insufficient to accommodate the data quality and bandwidth required in a mission critical telesurgery setup where unreliable data transfer could be catastrophic (Korte 2014). Third, the financial cost of robotic surgery is prohibitive in many remote locations. Finally, latency in communication speeds does present technical challenges. Perez et al. used the robotic daVinci Trainer to determine impact of communication latency on telesurgical performance (Perez 2016). As latency of data transfer increases, this appears to have an expanding effect on performance. Deterioration in

performance was initially identified with delays in data transfer of 300 ms with many surgeons being unable to perform complex tasks with delays greater than 700 ms. Ultimately, a dedicated, reliable, rapid connection with appropriate resources and personnel on the other end is required to ensure a safe procedure.

CONCLUSION AND FUTURE DEVELOPMENTS

Robotic surgery has become widely available throughout major cities globally. Initial costs of acquiring, setting up and training personnel in a surgical robotics program remain prohibitive in many areas of the world. Despite this, robotic assisted laparoscopic surgical platforms will continue to evolve and further penetrate surgical specialties, driven by a desire to conduct ever more complex operations at no incremental morbidity to the patient.

Surgical robots are unique in that they have the capacity to integrate and interface between other technologies widely used in the operating rooms. Preoperative imaging results (computed tomography or magnetic resonance imaging) can be integrated with the daVinci surgeon console to help surgeons more accurately target pathologies. Simulated complex procedures could also potentially be practiced prior to live surgery to improve outcomes (Lanfranco 2004). Furthermore, the original goal of long-distance surgeries might eventually become possible to bring care to remote areas with limited access to skilled surgeons.

The continued growth and development of new technological advances in medicine, coupled with the efforts of surgeons and researchers to further improve patient care will continue to fuel the development of new approaches to tackle procedures thought to be inaccessible. The expansion of the surgical robotics market with additional manufacturers will help lower the cost of entry for many institutions. Robotic surgery has demonstrated promising results thus far with respect to patient outcomes despite formal clinical trials and is likely to take its place in the standard armamentarium of patient care.

Chapter 201

HISTORY, DEVELOPMENT AND THE IMPORTANCE OF EXPERIMENTAL SURGERY

***Huifang Chen^{*}, MD, PhD
and Pierre Daloze[†], MD***

Laboratory of Experimental Surgery, Department of Surgery,
CRCHUM, University of Montreal,
Montreal, Quebec, Canada

ABSTRACT

It is an aphorism to say that surgery composes both science and art, only one of which still true. The Science has often competently made medical and surgical progress both in the clinic and in research.

In this chapter, the history of medicine and surgery is reviewed in Babylon, Egypt, India, China, Japan, America, Canada, Russia, and during the eighteenth and nineteenth centuries in Europe. The clinical history of surgery remains the basic element of medicine. All medical history in this chapter will guide students through by covering all routine clinical situations, and will give the students the courage and tenacity they need. It also includes a series of clinical cases where surgical skills can be improved. The introduction to confirm the information is efficiently estimated in the history of treatment of bleeding, pain, and infection. We sincerely hope that from this information, the student and resident doctor will learn faster in their initial steps on the way to becoming a proficient and caring professional.

Keywords: experimental surgery, Babylon, Egypt, India, China, Japan, Europe, America, bleeding, pain, infection

C.E.	Christian Era

INTRODUCTION

Modern surgery's success is the result of thousands of years of efforts by the pioneers encouraged by the same ideals as surgeons today. Chirourgia, is from the Greek, "cheir" meaning "hand" plus "ergon" meaning "work." A sixteenth century French surgeon named Ambroise Paré defined performing surgery as "to eliminate that which is overmuch, restore that which has been disjoined, separate that which has been integrated, join that which has been divided and repair the deformity of nature." (Bishop1960).

Bleeding, pain and infection were three major barriers for surgeons before the industrial revolution. Successes in these fields have reformed surgery from a delicate "art" into a scientific principle for the treatment of many kinds of diseases (Woodward 1963).

BABYLONIAN SURGERY

Babylonian medicine (Leonardo 1943) and surgery supposedly started off as the most primordial in nature. According to the records from unearthed cuneiform, diseases were assumed to be caused by evil essences and cures were obtained with the help of astrologers. Gradually, things changed and Babylonia became famous as a spiritual center around 2000 B.C. At that time, there was the constant existence of priests. Medical activity in this period also changed, accomplished by a medical god of the moon named Sin. Medical plants were picked up by moonlight to be used for medical preparation. Magic symbols played an important role even in the late Babylonian age.

One of the most famous documents of Babylonian medicine is named the *Code of Hammurabi* from about 2000 B.C. which detailed regulations about the legal side of the medical profession, but also described the usefulness of surgery in Babylonia. It was the first time dealing with operating fees in the *Code of Hammurabi*: "If a physician shall cause on anyone a severe operation wound with a bronze operating-knife and cure him, or if he shall open tumor (abscess or cavity) with a bronze operating-knife and save the eye of the patient, he shall have ten shekel of silver; if it is a slave, his owner shall pay two shekels of silver to the physician."

In spite of such details about management, nothing is known of Babylonian surgical techniques. At the beginning of seventeenth century B.C., the whole Assyro-Babylonian kingdom was destroyed by the war and almost all specific cultural practices and development were suffocated.

The Medes and Persians were a little more progressive in their medicine and surgery than were the Babylonians. Their book named *Zend-Avesta*, was written by Zoroaster himself. According to these fearful writings, the world is administered by good or bad spirits, and both

their religion and medicine were based on a dual deity. At that time, there were three classes of physicians, the knife, the herb, and the word professional, but because of the lagging behind of the three groups, when patients were sick they had to consult Egyptian doctors. At late age, they resorted to inviting the best Greek physicians. The next step in the evaluation of human surgery was in the Nile Valley, in the kingdom of the Pharaohs, where the builders of Pyramids were developing an essential system of medicine and where dogmatic circumcision was being started.

EGYPTIAN SURGERY

Because of literature records, we know much more about Egyptian medicine and surgery. The *Edwin Smith Papyrus* is one of the crucial and brightening documents in surgery which was written in about 3000 B.C., around as old as the Pyramids themselves. The book was standardized and written as a textbook of surgery and not mixed with magic of later centuries, but was incomplete. It started with injuries of the head and sprains of spinal columns, but was missing abdominal organs and lower extremities. Forty-eight ordinary cases were described and each one was carefully examined before the diagnosis was made. The manuscript was exceptional and impressive, and of high scientific class. In the case of an injured head, the pulse was recorded and a digital determination of the wound was attempted in order to decide whether there was a fracture of the skull in the intact surface. The surgeon should have been familiarized with the symptoms from the brain, and discouraged fractured fragment of the bony skull with an elevator. The treatment of wounds was considered to be quite modern, where the wound edges were placed close together and bandages obtained from an embalmer to hold them together in position. Fractures were nicely detailed and there was even excellent technical management, e. g., in the fracture of the clavicle, where the patient should lie flat on the back for a prolonged time, with a sand-bag between the shoulder-blades, a method which is often employed even today to ensure a good therapeutic result. All the details were specifically explained. Bandages and splints of linen soaked in glue were used. A crushed fracture of a vertebra of the neck, caused by an accident with the death of the patient, was specifically expressed and, in a lesion of the spinal cord, paralysis of intestines and bladder was reported (Smith 1972).

In the ancient surgical thesis, which was like “*Secret Book of Physician*,” it was advised how to treat a dislocated mandible. It showed directly how to place the doctor’s hands to reduce the dislocation. A manuscript of the Fourth Dynasty (2900–2750 B.C.) showed a drill-hole in the mental gap for the purpose of draining an abscess under a molar tooth for which specialized metal instruments, probably made of bronze was approved. Thus, in this age, surgical instruments already existed which appeared in the surgical treatise (The Oriental Institute of the University of Chicago 1930).

The original edition of *Edwin Smith Surgical Papyrus*, perhaps written around 5000 years ago, was an essential book for the practitioner. Another valuable medical commencement was *Kahun Papyrus*, found in Faiyum in 1889 by Sir Flinders Petrie. It mainly concerns gynecological subjects which were written around 2000 to 1800 B.C. The Brugsch Papyrus which was very small, consisted of many recipes, but was not very important for surgery. More important is Papyrus Ebers written about 1550 B.C. and found during exploration by

Ebers at Luxor in 1872 A.D. This collection contains many medical texts of various ancient periods, especially dealing with medical treatment. Ebers himself considered that Papyrus was one of the lost sacred books.

From the dig, Egyptians found a variety of instruments, such as knives, hooks, cupping glasses, needles, forceps, etc. These instruments, found in a tomb near Thebes, are characteristic of the Bronze Age. The *Ebers Papyrus* contains almost one thousand prescriptions and therapies. But they mostly contain elements which either were ridiculous or fill us with dread and esteem. In more ancient times, it seems that the real pharmaceutical preparations were known. Later, however, appeals and prayers, magic hymns and sentences had to prepare the prescriptions. In this age, the following wounds were treated; gangrene, pus, pustules, abscesses and especially tumors of different kinds (fatty tumors, abscesses of the neck, enlarged glands, mammary growth), hemorrhoids, and foreign bodies. How did they treat the wounds? They used perfect methods of dressing; bandages of linen, soaked with honey and myrrh, and all had to be removed four days after surgery.

The history of Egyptian medicine has other important sources of information such as hieroglyphics carved in stones and monuments. Many surgical instruments were unearthed, and the discovery of metallic sacred improvement, usually made of gold or silver, describing parts of the human body which presented evidence of deformity or damage. Furthermore, the dead bodies were embalmed and protected, so that both physicians and embalmers had the opportunity to learn the basic knowledge of human anatomy, especially the interior anatomy of the body. The first anatomy book is said to have been written by King A, the son of King Menes who was of the first dynasty that ruled in 5241 B.C. (Manetho) or in 5702 B.C. (Boekh).

From the Papyrus Ebers and other sources, we know that some, but not all Egyptian physicians were priests. Herodotus and Diodorus Siculus were our main sources for the positions of physicians in Egypt in the fifth century B.C. According to the document, Herodotus described: "The art of medicine is thus divided among them: Each physician applies himself to one disease only, and not more. All places abound in physicians; some physicians are for the eyes, others for the head, others for the teeth, others for the intestines, and others for the internal disorders." According to Diodorus Siculus: "in expeditions and journeys from the country, all treated free of charge, for the physicians received their salary from the state. They provided their services according to a written law compiled by many famous physicians in ancient Egypt...and if after following the laws from this sacred book they are not able to save the patient, they are safe from any allegation, but if they act contrary to the written law, they may expect capital punishment."

For dentistry, the Papyrus only showed a few prescriptions, but when they examined mummies, it showed that the dentist possessed a certain degree of background in conservative treatment and replacement.

Ophthalmic surgery was relatively deficient. The Papyrus mentioned only cleanup for trichiasis, known as conjunctivitis, inflammatory corneal opacity, abscess of cornea, epiphora, ptosis, myosis, ecchymosis of lids, and milium.

Circumcision and sterilization were old practices in Egypt as established by many headstones of most ancient origin and excavations from 4000 to 5000 year B.C. They showed circumcision on a series of male corpses. The procedure was generally used on girls consisting of excision of the prepuce of the clitoris. It is believed to have been performed on both sexes during the fourteenth year of age.

For centuries, Egypt was the world's principal contributor of sterilization, and castration was either performed by cutting with a knife of flint or by battering the testes to total extinction with a stone. Lithotomy was known from more recent sources and this surgery had been performed constantly for centuries. For many countries, these were a recognized part of medical and surgical training and practice.

Egyptian medicine from various sources and from many centuries of information formed the picture we have today. Priestly influences, tradition and cabalism, scientific cogitation and research were all incorporated later. Only when Persia became predominant did Egyptian culture, arts and sciences become plentiful for later generations, Egypt perpetuated some of the best medical and surgical conceptions (Tomnsend 2005).

CHINESE SURGERY

Chinese medicine and surgery were closely developed and connected with the history of Chinese advancements. There was an Emperor named Shen Nong who lived about 2700 B.C., who was respected as the chief god and primary architect of Chinese medicine. He was also respected as the father of acupuncture and medical herbs (Leonardo 1943).

There was plenty of medical literature recorded in ancient China. The most famous Chinese book was written by the Emperor entitled Huang-Di Nei Jing (2688–2599 B.C.) which represents the most ancient medical texts. Similar to other nations and countries, demonology and magic aided in the development of Chinese medicine. However, the influence of Chinese culture and philosophy gradually changed the exceptional cosmogony combined with a finding of experimentation that was designed into a kind of medicine which is totally different from any other nations except Japan and other Asian countries which were monopolized by Chinese medicine.

Confucius religion regulated the whole theory of the universe and hence also of medicine. The whole life is galvanized by two fundamentals: the positive *Yang*, which is always male and decisive, and the negative *Yin*, being female. These two fundamentals are always in the condition of balance and do not change with time. Yang means sun, force, light and heavenly quality. Yin means humidity, darkness, cold, etc. The domination of Yang or Yin regulates character, sex, sickness or prosperity. Yang, the male predominant, should always be an influence and in suitable relation to Yin. The Yin-Yang theory is still used in Chinese traditional medical practice at present.

Hua Tuo was a famous Chinese surgeon in Eastern Han and Three Kingdoms. He was the first surgeon to perform surgery with the aid of herbal anesthesia, around 1600 years before the practice was adopted by Europeans (Sherer 2004). Hua Tuo performed many laparotomies and the curettement of scapulas of soliders to cure caries of the bone. Bian Que (Pien Ch'iao) was a "marvel doctor" described by a Chinese historian named Sima Qian in his famous history book entitled Shiji, where he was cited with many skills. Another book entitled: Liezi (Tang Wen Pian) described that Bian Que exchanged two patients' hearts to cure their diseases (Kahan 1988; Graham 1961). This was a legendary story which means the concept of organ transplantation was fantasized around 300 CE ago in China (Schlich 2010).

Acupuncture and moxibustion are typical surgical procedures in the history of Chinese medicine which are currently in clinical practice. Moxibustion is a traditional Chinese

medicine treatment using *moxa* made from dry mugwort (*Artemisia argyi*). Modern scientific evidence does not prove moxibustion can prevent or treat cancer (list of unproven and disproven cancer treatment 2013). But it still be widely used in traditional medicine in China, Korea, Japan, Vietnam, and Mongolia. According to the ancient theory, the decisive Yang and Yin are contained in twelve hypothetical and invisible channels named Chin, which are situated deep in the musculature. This channel system is not directly connected with blood vessels and nerves but nevertheless influences the whole human body, particularly the blood circulation. The distribution of Yang and Yin, the vital elements, is always changing, but they keep balancing each other all the time.

Chinese surgery has not made big progress over the past 1,000 years, but fortunately it did during last century due to the peaceful invasion of foreign missionaries. Modern medical schools and hospitals were established in most of provinces of China, not only by European and American doctors, but also by Chinese co-workers who had learned the philosophy and scientific knowledge. Since 1949, the Chinese government has authorized a policy to combine western medicine with Chinese medicine. In each county, there is at least one Chinese medical hospital. In each province, there is one Chinese Traditional Medical School to train Chinese traditional doctors. In any western medical school, there are courses to train medical students to combine western medicine with Chinese traditional medicine. To date, Chinese medicine has been transferred to 171 countries and districts in the world, according to the statistical data from WHO (Chan 2014). Chinese medicine has been legally accepted in Australia, Canada, Austria, Singapore, Vietnam, Thailand, and South Africa, etc., a total of 29 countries and districts. There are 18 countries or districts that have accepted Chinese medicine as their health insurance system (Chan 2008).

The Nobel Prize winners in physiology or medicine in 2015 were William C. Campbell, Satoshi Omura, and Youyou Tu. A number of serious infectious diseases are caused by parasites spread by insects. Malaria is caused by a single-cell parasite that causes fever. Traditional Chinese medicine uses sweet wormwood to treat fever. In the 1970s, after studies of traditional herbal medicines, Youyou Tu managed to extract a substance, artemisinin, which inhibits the malaria parasite. Drugs based on artemisinin have led to the survival and improved health of millions of people (The Nobel Prize in Physiology or Medicine 2015).

JAPANESE SURGERY

As in other countries, Japanese medicine had a mythical period with demons and evil continuity in the early stages. Magical incantations, prayers and sacrifices were the sole treatment methods in the ancient period. Bloodletting, covering of wounds with sawdust, and other very primeval therapies were the surgical treatments (Traditional Japanese Medicine 2017).

Very early on (around 1500 B.C.), Japanese culture and medicine were influenced and impacted by Chinese culture and medicine. Korea was the link between China and Japan, transmitting not only Chinese medicine, mainly for Buddhist acquaints but also to indoctrinate (about 560 A.D.). Young Japanese doctors were sent to China to learn medicine sponsored by Japanese government. They learned midwifery, the treatment of wounds, bandaging and acupuncture. Hospitals took care of old and sick patients in the temple of Nara

and other associations. The Empress Gemmyo equipped the largest hospital for poor, sick people around 758 A.D.

Surgery in the Heian Period (784–1186 A.D.) mainly consisted of incisions and external abscesses with a knife, and cauterization of ulcers and dog bites. Abdominal surgeons liked using the bark of a mulberry tree to suture with threads the intestinal wounds, and also operated on atresia vagina.

The author named Fukuyoshi Omura in the Showa Era (834–847 A.D.) wrote the first dissertation on surgery, based entirely on Chinese surgery. During the Muromachi Period (1334–1568 A.D.), the wound surgeon emerged. Wounded soldiers and weak patients who were unable to do further military work learned medicine and took care of other wounded soldiers when the opportunity arose (Park 2012).

An important improvement was achieved when the Portuguese clergy came to Japan in 1568 A.D. Two physicians named Yariis and Geri-Gori, who belonged to this group, founded the “Surgery of the Southern Barbarian School.” They performed brilliant operations, treated the lepers and built hospitals. In 1585 A.D. the Christian religion was totally abrogated from Japan and all foreign physicians were discharged. Two Japanese students continued the practice of Portuguese medicine, settling in Sakai, and thus spreading foreign medicine by practice and by publication of medical books. Worthy of mention is a method of wound treatment and Gense Yamamoto’s *Mangai Shuyo*, a handbook of surgery. Other books were written by various authors concerning internal medicine, surgery, diseases of eyes, diseases of women and children acupuncture and moxa, mouth and tooth diseases, materiamedica and hygiene. 1765 was an important year for obstetrics because Gen-Etsu Kagawa published his work, and succeeded in taking away midwifery from midwives to the medical art.

In fact, Portuguese physicians had developed good and productive relations with Japan, at least for a certain period of time, which induced other nations to try the same. The Dutch were very successful establishing trade relations by starting a mission to come in contact with Japanese patients. In the seventeenth century, many Dutch medical books were translated into Japanese entitled *Geka Soden* (1706). Afterwards, Paré’s surgery was so demanded and definitive in Japan that it became almost equivalent with European surgery. Afterword, Dutch books were prohibited until 1702, then they were allowed again and their scientific knowledge was even promoted (1745).

A book on German anatomy, written by Johann Adam Kalmus was translated from Dutch to Japanese by several Japanese physicians, and other books followed. In the eighteenth century, there were many European medical books translated into Japanese, i.e., “*A New Work on Surgery*” or “*Yoi Shinsho*” by Gempaku Sugita and Gentaku Otsuki which mainly translated Lorenz Heister’s work. In 1832 the first institutionalized textbook on European surgery was translated into Japanese by Kincho Sugita. Many Japanese doctors followed and translated many medical textbooks. Medicine and especially surgery made great attainments during that time. In 1857, a medical school was established at Yeddo by Dutch physicians and then many medical facilities were established in the Kyoto Medical School and University of Tokyo. Soon, Muller, Hoffmann, Wernich, Gierke, Schultz, Baelz and others taught medical students in these institutes.

During the Meiji Period (1868 to the present), Japanese Medical Science closely followed Europe, America and international advances, building-up many modern medical centers, medical schools, medical institutes. Medicine and surgery are now distinctly state-of-the-art. Japanese medicine has given up the old methods as well as the transitory stage of learning.

The Japan of today has contributed international humanity by their medical practice and major medical research discoveries (Traditional Japanese Medicine 2017).

HINDU SURGERY

In India, the earliest Hindu medicine and surgery developed in the Vedic era. The Vedic era acquired the name from four *Vedas*, which create the Sanskrit language and literature and were nominated as the Rigveda, Yagveda, Sâmaveda and Atharvaveda (1500 B.C.). Among these four, Rigveda and Atharvaveda possessed medico-surgical interest. In this epoch, the surgery of ancient Hindus reached an outstanding level. Atreya, Agnovesa, Charaka, Dhanvantari and Susruta who were the students of the latter, were all the first Indian physicians. During that epoch, the most important medical text books were *Charaka-Sambita* and *Susruta-Sambita*. At that time, Susruta concluded a more succinct treatment of his practice and full consideration of surgery. Susruta classified operations into eight different kinds: incision, division, scarification, puncture, probing, extraction of foreign bodies, evacuation of fluids and suturing. A surgeon who intended to perform this kind of surgery should equip himself with the following tools: blunt instruments, cutting instruments, caustics, probe, horn, leeches, bitter gourd, a tent or bougie made of black stone, cotton, pieces of cloth, thread, jute leaves, honey, clarified butter, suet, milk, oil, emollient and astringent fluids, liniments, pastes, fan, cold water, hot water, iron pans and steady, calm and able-bodied assistants. Surgical operations should be performed on a propitious lunar day, star, and moment. The surgeon should be careful not to injure any vital part, vessel, nerve, joint, and bone.

Susruta enumerated 101 blunt instruments, the most important being the human hand. The instruments are usually made of iron. But sometimes made of other materials when iron is not available, like: “hooks, scalpels, scissors, saws, lancets, needles, probes, sounds, directors, trocars, forceps, syringes, catheters, bougies, vaginal and rectal specula.” All the instruments are accurately described for the shapes and applications. There were many kinds of sutures: “winding like a sling, continued and interrupted sutures.” And there were three kinds of needles: “round needles, three-sided needles, and abdomen and scrotum, a needle curved like a bow.”
